The role of transportation in economic development has also been addressed for each individual transportation mode and infrastructure. As an example, airports illustrate the role of transportation in economic development, considering the significant extent to which airports impact human society. Conventionally, it has been presumed that airports significantly promote economic growth and development in both direct and indirect ways. Directly, airports contribute to economic and employment growth because airport operations themselves generate job opportunities, for example, in management and operations functions. Indirectly, positions in supporting services arise: shopping vendors

within the airport and hotels outside of the airport need to be staffed. In addition, the presence of an airport could convince firms to choose a nearby location if they benefit from fast delivery of their products or easy national and international travel. Further, migrants who need convenient access to long-distance travel might find airports a deciding factor for relocation. Long-distance travel afforded by airports is more convenient than surface transportation via highways and railways and reduces limitations of distance on social and economic interactions. Overall, airport development can impact urban agglomeration, business competition, and job creation; the concept of the “aerotropolis” addresses this perspective.

The majority of studies investigating the impact of airports on population and economic growth have been conducted in metropolitan areas and concluded that airport activities enhance economic growth and development. For example, Michael Irwin and John Kasarda studied the causal relations between the presence of airline networks and employment growth in U.S. metropolitan areas. According to them, an airline network causes rather than results from employment growth. Jan Brueckner established that more airline service, such as is reflected by a high number of passenger boardings, significantly boosts urban economic growth. Richard Green found passenger boarding to be a powerful measure to predict population and employment growth in metropolitan areas. The few studies conducted in rural areas have yielded mixed findings. For instance, R. Rasker and colleagues revealed that access to an airport considerably increases economic development in high-amenity rural areas. Yet, A. M. Isserman, E. Feser, and D. E. Warren concluded that the distance to major airports is a relatively insignificant factor for economic development in rural areas.

Mixed Research Findings

However, empirical research does not unanimously suggest that transportation has a positive impact on economic development. The findings are sometimes disparate and contradictory. Some found positive impacts, some found no impacts, and some even found negative impacts. There are at least three possible reasons for this.

First, these studies have been conducted at different points in time, from preconstruction to construction

The Scottsdale, Arizona, municipal airport in 2013. It is a small but economically significant airport 9 miles from the city center. It is also surrounded by a portion of the Scottsdale Airpark, which is one of the largest employment centers in the state of Arizona, housing almost 2,500 companies that together employ approximately 48,000 people.

to postconstruction periods; in each of these phases, impacts of transportation on economic development could be different. During preconstruction, population growth and demand prompt the infrastructure investment. In the time of actual construction, either positive or negative impacts could result as construction represents an inconvenience that might deter people from moving in. Temporary closures of businesses sometimes become necessary, affecting local economic development. However, simultaneously, the increased future value attracts business to move in. The net effect depends on these factors as well as other demographic, socioeconomic, and biogeophysical determinants. During postconstruction, positive impacts are more likely, though they will fade over time.

Second, these studies have been conducted in different types of areas. Transportation impacts on economic development may vary spatially because

growth mechanisms, areal characteristics, and temporal contexts are likely to vary spatially across local areas. For example, in a study examining highway expansion impacts on population change in Wisconsin at the minor civil division level, Guangqing Chi found different impacts across rural, suburban, and urban areas: highway expansion has indirect effects on population change in rural areas, both direct and indirect effects in suburban areas, and no statistically significant effects in urban areas.

Third, these studies are conducted at different geographic scales. For example, immediate neighborhoods tend to view highways as a noise and pollution producer while neighborhoods just a few blocks away focus on the accessibility they provide. A study conducted at the block level is more likely to establish both positive and negative impacts than a study at the county level, in which positive and negative impacts cancel each other out.

Conclusion

Transportation impacts on economic development are a complicated topic. Readers may want to take a comprehensive approach when addressing the role of a particular transportation mode or infrastructure regarding economic development.

Economics of Air Travel

Economists have determined that the prosperity and downturns in the economy, which run in cycles about every nine to 11 years, also affect the airline industry. In general, national and global economies can have great influence on how well the airline industry prospers. The airline industry has had to maneuver around competition with other airlines, shocks to the system from recessions, and thin profit margins.

A good example of how overseas actions can affect the airlines occurred in Iran. In 1979 a revolution erupted to depose the U.S.-supported Shah of Iran, Mohammad Reza Pahlavi, who subsequently fled the country with his family. Not long after, in 1980, Iraq invaded Iran, and oil suppliers in the Middle East almost ceased operations. This created a worldwide panic that soon led to high inflation, higher oil prices, and a slowed economy. The airline industry worldwide suffered a net loss from 1978 to 1981; only when fuel prices returned to the price levels before the panic did they do better. Later on, airlines did well financially.

Since the airline industry appears to follow general U.S. economic success, the mid-1990s saw significant profits for the industry. But even during good periods, profits were not that significant. In 1998, though it was considered a good year, profits were still rather low; net profits, after accounting for interest payments and taxes, rarely achieved even 2 percent overall. But the demand for airline services continued to grow in the same time period.

The industry found its push for deregulation had both benefits and drawbacks.

Deregulation and Customer Service

Before the deregulation or liberalization of the American airline industry, it worked under a number of restraints. During the period from 1934 to 1978, airfares were strictly regulated by the Civil Aeronautics Board (CAB). The CAB did allow airlines to raise prices in order to cover costs but did not let them cut prices to compete with other airlines, or try to make fares more affordable for the middle class. In this way, the CAB actually stifled growth within the airline industry.

Regulation was intended to help maintain consistency in the industry. Although some markets had too much plane traffic and others not enough, at CAB insistence airlines flew direct routes between the same cities, whether the plane was full or not. Fare prices were based on the number of miles the plane flew, so a ticket from San Francisco to New York was about the same cost as a ticket from San Francisco to Hartford, Connecticut.

Unable to cut ticket fares, the airlines resorted to using other methods to attract customers away from the competition. In the 1960s they worked on offering better customer service, such as installing piano lounges and round tables where patrons could sit while waiting for a flight. Or they required their female flight attendants, then called stewardesses, to wear very short, sexy uniforms.

Before 1978 there had been bilateral agreements between pairs of foreign countries in order to control market access, such as points served, traffic rights, and, in many cases, also traffic capacity and travel frequency. This included scheduling of routes and points served so that there would be price controls in those areas. These agreements could also include interairline pooling agreements (or code-sharing) that allowed airlines to share revenue from routes they shared in common. An airline's resulting revenue would be equal to its capacity share, normally 50 percent. This option provided little incentive to compete against other airlines on the international scene, a possibility closed to airlines traveling the United States. Airlines were not allowed to enter into these kinds of agreements for domestic flights because they violated U.S. antitrust laws.

American airlines were eager to have fewer restraints. To gain more control over their industry

and greater access to various markets, the airlines lobbied Congress for deregulation, and they pointed out how Southwest Airlines, which back then flew only within the state of Texas and therefore was not under federal restrictions, had a successful "discount fare" operation. In 1978 President Jimmy Carter signed the Airline Deregulation Act, with the goal of reducing regulation to a bare minimum so that airlines could raise their profits. The Airline Deregulation Act did appear to help the airline economy. It allowed heavily traveled routes, such as between New York and Chicago, to reduce airfares, but at the same time it caused less-traveled routes, such as between Los Angeles and Santa Barbara, to increase fares for passengers. Although there was a fear deregulation would hurt the airlines' safety record, they did not cut safety measures when they cut airfares. Equipment failures and human errors decreased, while air travel, with many now-lower fares, allowed more people than before to experience flying on a jet plane.

Internationally, with the help of bilateral air services agreements, U.S. airlines now had greater access to possibilities previously closed to them. Those included greater opportunity for innovative methods of competitive pricing, elimination of restrictions on frequency and route operating rights, and banishment of unfair fare pricing by U.S. airlines abroad. The act also authorized U.S. cities, specifically, to be designated as international gateway cities and created more competitive air cargo services as well.

In 1992, amid concerns that many international bilateral agreements were actually becoming restrictive, the U.S. and Dutch governments signed the first "open skies" agreement. This assisted the U.S. airline industry further, because the agreement opened the other country to flights to any city in that country. It also provided multiple designations for airlines, no frequency or capacity control unless related tariffs were too high or too low, and enabled these airlines to share codes or other such commercial agreements as would benefit both parties.

This agreement occurred during the Iran–Iraq War, raising fuel prices during a slowing economy. After three years of record losses and bankruptcies, including the demise of Pan American and Eastern Airlines, the U.S. Congress in May 1993 established the National Commission to Ensure a Strong Competitive Airline Industry. The commission

recommended technological and institutional changes to help make it a more efficient industry as well as to improve air traffic control management operations. It also suggested the U.S. government renegotiate its bilateral agreements for even less restriction, for a more open, liberal market environment. The Bill Clinton administration assisted in this effort by endorsing a sole-carrier system, whereby the same airline provided end-to-end services on direct flights or to hub destinations, as well as joint carrier systems that offered connecting flights under code-sharing agreements.

Even with many U.S.-style open sky agreements in effect, the international community still was not totally deregulated economically. For example, in the United States, under so-called fly-America policies, officials traveling on behalf of the U.S. government were required to use only U.S. airlines and U.S. carrier code-shared flights operated by foreign airlines.

More Regulations on the Horizon

By December 1999, U.S. Transportation Secretary Rodney Slater decided to host a conference in Chicago with the theme “Beyond Open Skies.” The government wanted to go beyond open sky bilateral agreements. The European Union (EU) representative, Loyola de Palacio, was surprisingly receptive to the idea. She advised creating a Transatlantic Common Aviation Area, with the common goal of bringing the U.S. concept of open skies in line with the international open market. But no specific agreement was reached during this conference. The United States did permit transatlantic airline alliances, provided they were with European airlines that had signed open sky bilateral agreements with the United States, thereby allowing free entry into relevant markets. The EU was more proscriptive in its approach. It required that partnering airlines in relevant markets give up some runway slots to prospective competitors while also reducing their own frequency of use in any alliance, though they ran the risk of being anticompetitive.

An example of this policy would be changing the time and increasing travel frequencies, in order to make the market for the new airline in the agreement less attractive. This can be specifically illustrated by the U.S. antitrust suit against American Airlines in 1999. The government claimed the airline and its regional subsidiary AMR Eagle had driven three low-fare competitors—SunJet,

Vanguard, and Western Pacific—out of the Dallas–Fort Worth airport through consistent fare reduction and increased frequencies. The Justice Department claimed American Airlines was being “predatory” because the costs of the added flights exceeded their revenues. These cut-rate fares forced Vanguard to cut its frequency down to one flight a day and drove Delta Air out of that market entirely by May 1995. American Airlines defended itself, arguing it was just behaving as a tough competitor should in a very competitive market.

The “open skies” agreements worked for a while, but the problem of European markets still maintaining agreements more to their benefit needed to be worked out. In November 2002 the European Court of Justice (ECJ) issued a series of judgments with important consequences for U.S. airlines. The European Commission had brought eight infringement cases against eight of its member states regarding their bilateral agreements with the United States because of grave concerns on their part. The commission had maintained that it alone could negotiate these bilateral agreements, especially the open skies agreements, because they affected both the flow of traffic between the United States and Europe and created a distorted, contrary competitiveness between European airlines. Another piece of the legal case hinged on whether any EU national company could set up and operate a business in any other EU state.

As the case related to the United States, the ECJ ruled that EU members did have a right to individually negotiate bilateral air services agreements with U.S. airlines. But as legal problems still existed between EU member states concerning bilateral agreements, the United States would have to also modify its bilateral agreements with EU countries. After more legal wrangling and consultation between the European Commission and its member states, the Council of Transport Ministers of the EU adopted three pertinent, all-encompassing measures. First, the commission would be able to negotiate with the United States to fully liberalize (deregulate) air service between the EU and the United States, a move now considered and called “clear skies.” The European Commission would also have the ability to negotiate so-called horizontal agreements, which involved countries outside the European Union that had been mentioned in previous ECJ judgments, but these agreements would

not replace existing bilateral agreements. The third decision agreed upon in June 2003 enabled the Commission to prepare regulations on how air services agreements between EU states and third (outside) countries would be managed and enacted. These judgments have assisted the United States and other countries in their efforts to better serve their customers and business interests.

Labor Concerns

A big financial issue in running an airline well concerns labor. Strong unions and government-owned airlines with union strength have made airline management wary of labor's power, which is not something they can easily control. In the early 1990s, as losses increased, so did pressure to find an avenue to reduce costs. Some European airlines had actually received government funding to help with wage issues, while U.S. airline executives were offering labor share options in the airlines and expecting big wage concessions in order to stay in business. Since that time, labor—a major overhead cost—has continued to be a worrisome issue for airline management.

There are also great variations in labor costs, if one examines several airlines within a region. A review of labor costs in 2002 showed that for larger North American airlines, labor costs have generally ranged from 25 to 31 percent of total expenditures for the airline. For Korean Air, labor expenses were only 11.7 percent of total expenses; British Airways' labor costs amounted to 24.3 percent; Air France was near the top, with labor costs at 33.5 percent of expenses.

What accounts for these percentage rates? Many factors come into play. Prevailing wages in the airline's home country can make a difference, and staffs in different parts of the world can command very different wages. The 2002 review found Air Canada pilots/copilots made \$99,000 a year, compared to SAS pilots at \$200,300 a year. Cabin attendants for U.S. airlines earned \$44,000 a year, compared to Thai Airways' attendants, who earned \$17,800 a year. Flight equipment, type of aircraft flown, overtime payments, and pension and social security funds also add to airline costs and affect wages and company profits.

After the tragic events of September 11, 2001, when planes were crashed into and destroyed the Twin Towers in New York in an act of terrorism, the airline industry and the economy in general

went into a downward tailspin. From that December to December 2004, major airlines lost, on average, 29 percent of their labor force. There was not only a drop in demand but also a threat to low-cost "discount" airlines like Southwest and JetBlue. Since that time, management has found it necessary, at least in the United States, to renegotiate salary levels and conditions of employment periodically, as the economy goes up and down. Passenger behavior has also unwittingly led to cuts in airline support personnel. The popularity of purchasing airline "e-tickets" via the Internet, without travel agency assistance, led to travel agents' market share from 2000 to 2002 decreasing from 68 to 55 percent of bookings; this has continued to decrease in subsequent years.

Profits and Competition

What is the bottom line for the airline industry then? It all depends on the airlines' ability to fill the seats in a plane. If a plane takes off with empty seats, it is considered a missed opportunity; airlines ideally want all seats filled to maximize their earnings. To maximize earnings, they aim for a balance between filling part of the plane with discount fares and the rest with those passengers who have paid the full price for tickets. Airlines also take into consideration peak vacation travel times in their pricing schemes and offer lower cost incentives for flyers to travel on nonpeak days like Tuesdays and Wednesdays, or offer less flexible, nonrefundable tickets purchased far in advance. This may explain why a business executive needing a ticket several months in advance is charged much more than someone surfing Internet Web sites such as Expedia.com or Kayak.com and purchasing a ticket online only a few weeks in advance for several hundred dollars less on the same flight.

Competition, especially coming from deregulation, has not been beneficial for all the industry players involved. During the period from 1978 to 2002, there was fierce competition between different carriers for major routes like New York to London. At the same time, there was very little competition at some airports. Smaller or less traveled airports often suffered; where once several airlines served a small regional airport, now they had only one major airline to go by and at whatever price the airline offered. Of the 11 major airlines that existed in 1978, six have either gone out of business or merged with other

companies: Braniff, Eastern, National, Pan American, TWA, and Western. USAirways is presently planning a merger with American Airlines.

Underserved Markets

Federal transportation and aviation data show the United States has 19,700 airports operating in the country. Of these, 5,170 are open to the general public, but only 503 airports offer commercial service (CS). Of the 503 CS airports, 382 are considered primary airports. This is significant, because primary airports have over 10,000 enplanements a year. Important to primary airports are those considered conveniently located “hub” airports, from which many flights connect to other destinations. There are 29 large hubs in the country, which experience more than 1 percent of the total enplanements annually. At the other usage end are 244 non-hub commercial airports, where fewer than 10,000 passengers pass through a year.

In recent years these nonhub airports have been served more, with the emergence of commuter, shuttle, or regional flights, many of which use smaller, turboprop jets (that have propellers and turbines). A turboprop like Delta’s Embraer EMB-120 craft, which seats 28, is versatile, able to fly from bigger “hub” airports with many connections, like Charlotte, North Carolina, to serve smaller airports with less traffic, like the Tricities Airport in Blountville, Tennessee, or the Roanoke Regional Airport in Roanoke, Virginia. AirTran also flies to smaller markets like Austin, Texas, and Jacksonville, Florida.

Different economic climates, as stated above, affect the airlines. Even in smaller markets, so-called discount airlines, like Southwest, may charge more, as the price of fuel and other fixed costs go up. No airlines are planning to create another Concorde line, a special supersonic, super-fast jet Britain and France sponsored until 2003. Although it could travel from New York to London in mere hours, it used two tons of fuel just taxiing the runway; the horrible crash of one Concorde near Paris in 2000 discouraged many passengers from ever using it again. But the airline industry is adaptable and continues to seek ways serve the public while also making a small profit.

Economics of On-Street Parking

Parking is one of the largest components of the surface transportation system, and certainly one of the largest components of automobile ownership and use. Although many transportation analysts focus on problems caused by moving vehicles, such as congestion and pollution, automobiles also cause problems when they are stationary, because they demand an incredible amount of space for an extremely long time.

One advantage of the automobile is the autonomy it provides; a person with a car, unlike a person with a train or airline ticket, can go wherever she wants whenever she wants. Yet, this freedom from others’ routes and schedules—the freedom to take a car almost anywhere—means there must be room to store cars almost everywhere. Further, most cars are parked most of the time. Though people are seduced by speed and motion when buying vehicles, the average American automobile spends over 95 percent of its life parked. Estimates of the total amount of land in the United States devoted to parking vary but range from 500,000 acres to 11 million acres, or two or three spaces for every vehicle.

Scholars who study the economics of parking focus on the tension created between scarce urban

space and parking's high demands on that space. Much of this tension arises because drivers want parking to be free, and most local governments work to accommodate that desire. In doing so, almost all local governments make two decisions about parking, and both of them—to economists, at least—are mistakes. First, city governments mistakenly price street parking, keeping it free or cheap. Second, they react to the problems caused by that mistaken pricing by requiring developers to provide more parking off-street.

In this way, cities compound a policy that distorts people's driving decisions (offering free or underpriced street parking) by adding a policy that distorts the decision to build. Driving becomes cheaper, but housing becomes more expensive, and the supply of parking steadily rises, making vehicle ownership and use cheaper still. This cascade of bad consequences could be avoided if cities simply charged a market price for curb parking.

Price-Controlled Parking

Curb parking spaces are real estate, and, like all real estate, their value depends on location. A space that provides access to many people, jobs, and amenities—for instance, a parking space in Manhattan—is more valuable than a parking space that provides access to few people, jobs, and amenities. The access offered by a parking space varies both spatially and temporally. A Manhattan space is more valuable at mid-day than at midnight and more valuable at any time than a space in, say, Bozeman, Montana.

Yet, the price of curb parking rarely varies by time and location; price does not reflect value. Most of the time parking on the street—in Manhattan or Bozeman—is just free. Good things rarely happen when governments divorce price from value, and parking is no exception. Underpriced curb space leads to shortages.

At busy times, drivers cannot find curb parking spaces, and complain that the city has “no” parking. In frustration, they circle the nearby blocks, a phenomenon familiar to anyone who has done it or who has had the misfortune of being stuck behind someone doing it. This circling, which is known as “cruising,” has high costs. Travel is beneficial when it helps people get where they are going. Cruising is pure social waste; the people cruising have already arrived and are just adding extra vehicle miles (and imposing extra pollution and delay on everyone

else) in the hope of paying less to park. Perhaps most perniciously, cruising makes neighbors fearful of new development. Existing residents associate new residents or workers with more competition for street parking, and this fear of parking spillover fuels opposition to new building.

Minimum Parking Requirements

One might hope that cities would solve the problem of underpriced curb parking by removing the price controls and charging a price for parking that reflects its value, but one would be disappointed. All too often, cities respond to perceived shortages of curb parking by instituting minimum parking requirements—provisions in the zoning code that require developers to provide off-street parking with everything they build. A typical minimum parking requirement might force a developer to provide one parking space on-site per apartment, or three parking spaces per 1,000 square feet of commercial space.

Minimum parking requirements shift the cost of parking away from drivers and onto developers and therefore hide one of the largest costs of driving inside the cost of housing and other construction. Cities seek to solve a problem of allocation on public streets (a shortage of curb parking) by mandating provision on private land. The results are perverse. Research into minimum parking requirements consistently finds that they are associated with more vehicle ownership, lower levels of housing density, and lower levels of population density.

Housing built on parcels subject to parking requirements has more parking than housing built in deregulated areas, and it also tends to be more expensive. Minimum parking requirements do not, however, appear to solve the problem they were designed to address, which is congestion at the curb. So long as street parking is free, people will park there. Parking requirements have given us a landscape of full curbs and half-empty parking lots.

Market-Priced Curb Parking

The original sin in parking policy is the failure to accurately price the curb, and ending the practice of price-controlled parking could stop the chain of undesirable consequences that flow from it. The keys to this approach are to overcome resistance to pricing and then to price for performance rather than revenue. Pricing is rare, and in most instances,

cities set parking prices based on a desired amount of revenue. The system would work better if cities decided on a target occupancy rate, and then let prices float to achieve that rate.

Suppose a city decided that it wanted one or two spaces on every block to always be vacant, but no more than that. In such a system, the price of parking would be more on Monday than Saturday, more at mid-day than at midnight. Modern meters allow prices to rise and fall across and within days, so pricing of this sort is possible.

Some drivers would pay more than they do now, but they would receive a high-quality service for their money: vehicle trips that end not with cruising and frustration but instead in an easily found empty space near their destination. Less cruising means less pollution and congestion, and with cruising reduced, the need and justification for minimum parking requirements would disappear. Cities could pull the price of driving out of the housing market, and developers could build housing unhampered by costs that more appropriately belong to drivers.

Efforts at market-priced parking are growing but remain rare. Street parking has been free or underpriced for so long, in so many places, that charging for it can seem politically perilous. Yet, cities cannot maintain current practices forever. Governments can hide costs but not make them disappear, and ultimately, cities may need to decide that drivers, not developers, should pay for the costs of storing vehicles.

Elderly and Disabled Travelers

It is widely acknowledged that elderly and disabled travelers face a number of difficulties in accessing and using both public and private transport systems. Much effort has been focused on making modifications to physical infrastructure and vehicles and making reasonable adjustments to services in order to enhance their accessibility, and this has served an important role. In addition to this, however, the emergence of new technological opportunities is offering new potential solutions to transport inaccessibility but also new potential problems of inaccessible technologies. Making best use of the technological possibilities for enhancing transport accessibility is a challenge, but one that, if it is met, offers enormous scope to improve mobility, health, and well-being.

The World Health Organization (WHO) estimates that there are over 1 billion disabled people worldwide and highlights that this figure is on the increase and predicted to continue to grow in the coming years. The upward trend in disability stems from the trend toward an ever-aging population and the higher risk of disability among older age groups and the increasing prevalence of chronic health conditions, such as diabetes, cardiovascular disease, cancer, and mental health disorders.

In most parts of the world the proportion of older people within the population is increasing. As the population ages, the likelihood of impairment increases. How one defines "disability" can become contentious, depending upon the extent to which it is viewed as a medical issue or a social issue; that is, whether the source of disability is viewed as emanating from the individual's medical condition or from society's failure to organize itself in a way that accommodates the diversity of the population. Nevertheless, there is widespread acknowledgment that

disabled people face a range of barriers to accessing everyday goods and services, such as transport, housing, and education, and that these barriers result in diminished life opportunities for disabled people. For example, disabled people tend to have poorer health outcomes, lower educational attainment, lower employment rates, and lower incomes than nondisabled people. Consequently, there is a widespread acceptance that efforts should be made to reduce or remove these barriers, and many countries have passed legislation to enforce and embed such efforts. At the global level, the United Nations has put in place the Convention on the Rights of Persons with Disabilities (2008).

In terms of barriers to travel and transport, the principal response at first was to provide alternative transport services designed especially for disabled people, but as these specialized services became increasingly difficult to scale up and as the broader agenda turned more toward the inclusion of disabled people within the mainstream of society, attention turned to developing a more inclusive approach to travel, with the focus on tackling the specific barriers to access within mainstream transport services.

Five types of barriers to access can be distinguished: physical design (of the built environment and of transport infrastructure and vehicles), transport service availability/proximity, financial affordability, information and awareness, and training.

New Technologies

The following broadly adopts the categorization set out in the Organisation for Economic Co-Operation and Development's 2003 report, "New Transport Technology for Older People," which remains a very relevant document even now. This makes a three-way division of technological applications, as they are applied to a vehicle, a person or to the physical infrastructure.

In-vehicle systems. In-vehicle systems for private cars have generally been developed by motor manufacturers based on commercial incentives to increase driver safety, confidence and comfort, with an awareness of the growing size of the older driver market.

Adaptive speed control. Linked with Intelligent Sped Adaptation, this technology serves to help

Blind visitors to Olomouc, Czech Republic, in 2011 use their hands to learn the layout of the city center from an outdoor model that serves as a three-dimensional map for the visually impaired. Higher tech options in development include Blind Square, a smartphone app that links with the app FourSquare.

drivers maintain safe following distances even as the traffic ahead changes speed. Maintaining a safe following distance reduces the chance of a rear-end collision, and this technology serves to compensate for reduced reaction times on the part of the driver. Three levels of intervention are possible, ranging from the provision of an alert to the driver, to regulation of the throttle, to automatic application of the brakes. Tests have demonstrated the success of these technologies, though there are some problems of user acceptance associated with drivers' unwillingness to delegate active driving roles to the in-car technology.

Night vision displays. Employing a specialised camera to project an intensified image of the view in front onto a Heads Up Display (HUD), these systems serve to augment diminished nocturnal acuity and/or to enhance the range of sight. The HUDs

can also be used to provide additional overlaid information, or even augmented reality views to aid the driver. In this way, they can compensate for the deterioration in night vision often experienced with aging and safely reduce the older driver's tendency to self-regulate their driving behavior by minimizing night-driving.

Navigation systems. Now fairly commonplace, navigation systems combine satellite tracking and digital mapping to provide navigational assistance to the driver. Perhaps of particular help to the older driver whose ability to recall routes or to orientate in unfamiliar surroundings may be diminished, they can also be configured to direct them to less-busy roads, to avoid difficult junctions, and to provide advanced warning of lane-changes. However, there are also a number of concerns raised regarding the human-machine interface and whether the devices are designed appropriately for the older driver, regarding the extent to which a navigational aid becomes a driver distraction, and regarding the accuracy of the mapping information used.

Gap-estimation aids. These technologies measure the distance and speed of oncoming traffic at intersections and then provide a visual and/or auditory alert to the driver when it is safe to turn across the oncoming traffic. Accident statistics have shown older drivers to be over-represented in intersection crashes, probably linked with the declines in vision, cognition and reaction-time associated with aging, and it is thought that these technologies could serve to mitigate these problems.

Workload management systems. With the multiplicity of demands on driver attention, workload management systems seek to integrate and regulate in-vehicle systems and the signals, alerts and information they send out. The key to their function is said to be the inference of cognitive load based on vehicle data, enabling the prioritization of the different in-vehicle systems such that undue demands are not placed on the driver. Examples could include an automatic moderation of the volume of the in-car audio system when the navigation system detects a complex intersection, or the diversion of an incoming phone call to voicemail when heavy rain is indicated by the windscreen wipers being on full.

Personal Technologies

Personal technologies are being used to develop solutions for different disability groups. A great deal of effort has focused on technologies to assist visually impaired people. To a lesser extent, solutions have also targeted wheelchair users and others with reduced mobility and people with hearing or other communications impairments.

Smartcards. Smartcards provide for easier and more convenient transport-related payments, for example, for parking, for public transport, for paratransit and/or for taxis. They remove the need to sort through coins or bank notes, something which can be difficult for those with impaired dexterity or sight/touch. Contactless smartcards, based on RFID technology, can even be used without requiring users to remove the card from their pocket or wallet. Furthermore, smartcards can also be used to store customized accessibility-related information relating to the user, which could be shared with, for example, on-bus systems as a means of communicating with the driver or of reconfiguring a car's in-vehicle system for the particular requirements of that elderly or disabled driver.

Personal navigation aids. There are two main categories of personal navigation aids: those that provide passenger guidance and those that offer tailored accessibility-related information.

Passenger guidance for visually impaired people seeks to make use of satellite navigation technologies, in conjunction with screen magnification and speech synthesis technologies, in order to provide route navigation and wayfinding information to people with a visual impairment. Passenger guidance based on GPS and mapping technologies, often referred to as personal positioning systems (PPS), has been implemented in two principal ways. First, for much of the past two decades, implementation has been via specialist devices, designed for visually impaired people with the dedicated purpose of providing passenger guidance; the Trekker Breeze is the most recent example of this. While the portability of these devices has improved over time and their price has reduced, their purchase price is still in the range of 150 to 400 euros. Second, implementation has more recently been via applications (apps) designed for Internet-enabled mobile phones and smartphones, because the required technologies

are often already integral to the mobile device. The following are three examples:

- *Navigon*. This uses the mobile device's GPS capability and links with digital mapping to provide a fully functioning mobile navigation system, enabling text-to-speech voice guidance, turn-by-turn pedestrian directions, a "take me home" function, and links to the user's contact list to provide directions to a selected contact.
- *Blind Square*. This uses the IOS device's GPS capability to determine the user's location and then links with FourSquare and Open Street Map to look up and provide, in its synthetic voice, information about nearest street intersections, nearby shops, restaurants and other facilities, and distance traveled.
- *SeeingAssistant-Move*. Launched in 2013, this provides for route planning and route recording, advanced neighborhood scanning with world directions, location search, "where-am-I" functionality, input of sharing points, and use of voice commands.

Furthermore, the Royal National Institute of Blind People (RNIB) have been conducting groundbreaking work in the areas of augmented reality, electronic recognition and artificial vision. They see these as forming part of a "blended technological" solution, whereby technologies serve to complement techniques already being used, such as the long white cane and the guide dog.

Tailored accessibility-related information and communication apps for wheelchair users and other people with reduced mobility draw on digital maps and crowd-sourced data, often provided in real time. Examples of some of these currently on the market are as follows:

- *Jaccede*. This app was launched in 2012 and enables users to search for places that are accessible to those with a disability. Information, such as whether the entrance is step-free and accessibility of toilets, is displayed alongside photos, user comments, and other relevant information. Users can contribute by adding accessible places anywhere in the world or by editing

existing listings. The app was a winner of a Vodafone Smart Accessibility 2012 award, in the mobility category.

- *Assistmi*. This app can be used by disabled people to alert participating sites, such as shopping centers, railway stations and airports, to know when they are on their way and when they have arrived, while conveying all their access needs so they can be met by staff and properly accommodated. In addition, the Parking Space Finder function can help locate nearby Blue Badge (disabled parking) spaces and indicate how far away the space is, any special parking restrictions the space may have, and what kind of parking it offers.
- *GoGenie*. This app aims to help disabled and deaf people find access information online for any location, such as a shop, cinema, cultural event or town centre, based on the recommendations and comments of others. Specific features include access information, contact, maps, facilities to add reviews, photos and videos, and a "report-it" feature enabling people to complain directly to inaccessible venues and organizations.
- *Ldn Access*. This app is designed to be used as a source of access-related information for places to eat, hotels, entertainment, attractions, etc., throughout London. It is targeted slightly more broadly at disabled people (either physically or nonphysically or both), older people, families with young children, and visitors to London, and provides information on wheelchair access, disabled toilets, induction loops, baby changing facilities, customer parking, etc.

Physical Infrastructure

New technologies have also been embedded into the physical infrastructure of the built environment. Triggered Information, via the use of Beacons, has been the subject of research and development, and the RNIB has recently launched its update to their REACT system of talking beacons for visually impaired people. A further idea is that of "electronic leadlines," whereby RFID tags are fitted to the visually impaired person or to their long white cane, which then interact with tags in the environment.

The aim is to enable the visually impaired person to be prompted and guided in unknown environments, but it could also serve to improve cognitive awareness of one's surroundings. The Austrian "ways4all" project has undertaken ground-breaking work in this area, establishing several demonstration sites in Vienna. However, it is not possible to embed RFID tags everywhere, so the question returns to the issue of how to use what is already there to best effect.

Limitations

There are several scientifically exciting technological developments taking place, but a number of difficulties remain. Acceptance of new technology, particularly among older age groups and lower income groups seems to continue to be a problem. Likewise, technology abandonment has been shown to be commonplace, particularly where that technology has been designed especially for the elderly and disabled market. This would seem to be a result of several factors, including awareness of the technologies, cost to the individual, accessibility/user-friendliness of the technology itself, and a lack of availability of training specific to the technologies.

Add to this the problem of battery life for the devices, and it would appear that new technologies might be best seen as providing a complement—albeit a powerful one—to a travel environment that is itself inclusively designed.

Elderly Driver Safety Issues

Elderly drivers have higher accident rates than other age groups and are considerably more vulnerable to injury. Driving at an advanced age carries added risks due to limitations to perceptual, physical, and cognitive functioning. Specific medical conditions and the use of some medications can also increase the risk of accidents. The increase in the number of older drivers poses ethical questions at the level of public policy, as the objective of ensuring road safety must be balanced with the need to provide older people with the means to have independent mobility, which is linked to life satisfaction in this age group. Regulations regarding driving license renewal and assessment of driving ability are in effect in most countries. However, policies have also been designed to promote the inclusion of drivers in a safe road environment, through education and training. Developments in vehicle and road design may also contribute to ensure the safety of older drivers.

As a result of the increase in life expectancy and decline in birth rates, a large proportion of the population in developed countries is of an advanced age. General improvements in health and income also mean that more elderly people are now driving, both in absolute numbers and as a proportion of all drivers, while sociocultural changes have led to an increase to the proportion of older women drivers. In most countries the accident rate of elderly drivers is relatively high but lower than the rate of the youngest drivers (aged 16–24). In addition, because older people drive less than younger drivers, they are responsible for a smaller number of accidents. Nevertheless, elderly drivers are a special group of concern in terms of road safety because they are more vulnerable to injuries. In fact, the probability of long-term disability and mortality tends to be much higher for older drivers involved in car

accidents than for younger drivers, mainly because of their frailty. Safety issues are especially relevant for the older elderly (over age 75).

The cause of accidents involving elderly drivers tends to be specific to this age group. A large proportion of accidents can be explained by errors and lapses, such as failure to stop at red lights and stop signs, to give or yield right-of-way, and to respect other road signs. Other common causes are vehicle maneuvers in dangerous or confusing road environments such as sinuous road alignments, multi-lane roads, and complex intersections.

On the other hand, statistics and surveys show that older drivers adapt their driving patterns to compensate for some of the limitations they face. This includes driving slower, allowing wider gaps for merging with traffic, and avoiding driving in complex road environments, at night, under poor meteorological conditions, and on roads in poor state of repair or with wet and icy surfaces. Factors causing accidents in other age groups, such as excessive speed and driving under the influence of alcohol and drugs, are relatively less important in the group of older adults.

Functioning

There are several factors limiting the driving ability of elderly people. The aging process reduces the individuals' perceptual functioning. The most researched aspect regards losses in visual abilities. Older adults face limitations in terms of contrast sensitivity, night vision, ability to perceive detail, reduced visual field, depth and motion perception, and recovery time from exposure to bright lights. These factors influence the drivers' perception of road signs and of other elements of the road environment and limit their awareness and assessment of speed and distance from other vehicles, especially when compounded with limitations in other sensory processes such as hearing. Limitations in visual abilities also intensify the accident risk caused by driving at night or in foggy or rainy weather.

Physical functioning is also limited in older adults. This includes aspects such as strength, flexibility, and coordination. The ability to move parts of the body is crucial to driving. Restrictions to the motion of the neck increase the difficulties in seeing road signs and in assessing the different elements of the road environment. Joint stiffness may also limit the speed and coordination of movement. This may

reduce control of the vehicle, such as the ability to use the steering wheel to veer the vehicle and to use feet to control the accelerator and brake pedals. All these aspects can influence elderly drivers' reaction times to adapt to unexpected events on the road, a factor that is crucial in many road accidents.

The limitations to perceptual and physical functioning become more relevant for driving safety when in conjunction with limitations to cognitive functioning. Older drivers are more likely to suffer impairments in the capacity for concentration, speed of information recognition and processing, and short-term memory. Losses of attention and problems in sorting different types of information can also cause problems due to the distraction caused by the presence of disparate elements competing for the driver's attention on the road, such as road signs and other vehicles, while controlling the vehicle. This increases the probability of misjudgments leading to making wrong decisions and prolongs reaction time.

Elderly drivers are also at an increased risk due to the effects of the progression of specific medical conditions. Dementia and other neurological conditions are related to the probability of making errors while driving, as they contribute to the loss of attentiveness and failures to obey traffic rules and make the right decisions. Conditions impairing visual perception, such as cataracts and glaucoma, also have a marked effect on accident risk, as they contribute to the loss of visual acuity and the reduction of the visual field. Conditions impairing flexibility, such as arthritis, are also relevant because they affect the ability of the driver to control the vehicle. More research is needed on the effects of other conditions that are relatively more common in old age, such as metabolic, cardiovascular, and cerebrovascular diseases. More knowledge is also needed about the way that some of the medications used to treat some medical conditions prevalent in old age interfere with driving, especially the interacted effect of several medications.

Policy

Whether public policies should or should not promote driving in old age is an ethical question. The increase in the number of elderly drivers increases the risk of accidents for all road users, which has substantial costs for society as a whole. The problem is bound to become more serious in the future as

the number of active older elderly tends to increase. On the other hand, driving cessation has important psychosociological aspects. Driving allows for independent mobility, which is a critical component of the physical, mental, and social well-being in this age group. In dispersed suburban and rural communities, the car is also the major and sometimes only mode of transportation. The ability to drive also contributes to freedom and autonomy to a great degree. Elderly people who cease to drive may therefore feel they are losing independence and suffer role loss. Public authorities should thus consider the balance between the promotion of driving in old age and the application of policies providing alternatives for the lost mobility when individuals cease to drive, including the supply of public transportation, decentralization of facilities, and improved communications.

Regulations

Most countries have regulations regarding the driver's license renewal of older individuals. The issue is often subject to public discussion as there is no consensus regarding the specific role of age in accident risk. As such, regulations are not based exclusively on the driver's age and involve a mandatory assessment of their driving ability. However, the frequency of this assessment usually increases with the age of the driver. The evaluation process usually includes tests of visual acuity and other relevant abilities and may also include on-road driving assessments.

The evaluation of the ability to drive can also be made at the level of general clinical screening, usually in the case when a specific medical condition is identified. Guidelines for this assessment are in many countries provided by medical associations and transportation authorities. The *Physician's Guide to Assessing and Counseling the Older Driver*, published by the American Medical Association and the National Highway Traffic Safety Administration, is one example.

The application of strict regulations for renewal of driver's licenses for elderly people is often controversial due to the psychological factors involved in cases where the individual fails to pass the test; this may trigger depression and accelerate physical decline. Critics of this type of regulation point to the fact that in many cases there is opportunity for attempting a correction of the impairments in perceptual and physical impairments that limit

driving, while acknowledging that psychological support is also needed when the only option for the regulator is to revoke a driver's license.

Education and Design

Safety for driving older adults can be enhanced by education and training programs organized by public authorities and other organizations. The content of these programs usually includes an update on traffic laws, vehicle characteristics, and road environment, as these elements may have changed since the time when the individual learned how to drive. The programs may also include training regarding the specific limitations on driving caused by old age and tips to help drivers to develop strategies for identifying hazardous road conditions and driving behaviors. Training programs can also help individuals to prepare for driver license renewal tests and cover practical issues regarding the necessary procedures.

The safety of older drivers can also be enhanced by improvements in both vehicles and road designs. Vehicle manufacturers can add equipment to address specific old-age-related limitations, such as adjustable steering and brake and accelerator pedals, flexible and comfortable seating and safety belts, and larger windows and rearview mirrors. Devices such as geographic information systems and night vision enhancement can also provide useful information to help the driver to safely navigate the roads and steer the vehicle. The design of roads should also take into consideration the needs of elderly drivers, especially in the neighborhoods where the majority of the population is elderly. Important factors include lighting at intersections and the size and legibility of road signs and markings. Finally, the application of some traffic rules for all drivers, such as the mandatory use of daytime headlights, may also contribute to the safety of elderly drivers.

Electric Diesel Locomotive

Electro-diesel or dual-mode locomotives are locomotives with the ability to draw power either from their diesel engine or from an electricity supply (typically provided, as with all-electric locomotives, by overhead lines or a third rail). Diesel engines work like those of conventional diesel trains, by burning diesel fuel to power a generator that produces electricity in order to run electric motors in the wheels. Though they are not in widespread use, they have the obvious advantage of being able to reserve diesel consumption for those times when no electricity supply is available, reducing overall emissions. They also permit movement through areas where diesel engines are banned.

In addition to electro-diesel locomotives, which are railway cars that serve no function except to provide locomotive power for the train as a whole and have no payload capacity, there are electro-diesel multiple units, which are self-propelled railway cars that may either travel on their own or link up to other cars and be controlled by a locomotive. (This is not to be confused with the similar railway term, *multi-unit control*, referring to the process of controlling multiple locomotives.) While multiple units are not commonly used in long-distance railways in the United States, they are common in light rail and commuter trains, some of which are electro-diesel.

Low-speed trains sometimes use a primarily electric design, coupling an electric locomotive with an auxiliary diesel prime mover. This type of design is mainly used for rail lines that have brief gaps where electrical power is unavailable. At the other end of the spectrum, some primarily diesel trains are equipped with auxiliary electric motors for use where diesel engine use is banned. For instance, in the United States the confined spaces and heavy train traffic of

Penn Station and Grand Central Terminal have led local authorities to ban diesel emissions in those stations. Entering locomotives switch over to electric, drawing power from the third rail, before retracting the third rail "shoe" (the connection that draws power) when reentering diesel-friendly zones. In both these cases, the train is primarily diesel or electric, with the other mode used to provide power in a limited set of circumstances when the main power source is unavailable. Historically, most electro-diesel locomotives have been one of these two types. Full dual-mode electro-diesels have become easier to design, build, and operate as computers have improved transportation technology, and are often equipped with onboard computers that automatically adjust between modes as circumstances dictate. Full dual-mode electro-diesels are better suited to long-distance routes and have been advocated as a transportation solution for 21st-century America.

One of the earliest electro-diesel locomotives was the General Electric three-power boxcab, developed in the 1920s and called an "oil-electric" because of the unpopularity of German terms such as *diesel* in the post-World War I years. The boxcabs could switch between diesel and electric as described above but could also run on direct current electricity provided by batteries. Dozens of the locomotives were made, but production fell off when the Great Depression began. The three-power boxcab is similar in some respects to the modern hybrid locomotive.

Hybrid locomotives are an improvement on older electro-diesel designs, using ultracapacitors and modern fuel cells, and are reminiscent of hybrid motor vehicles. Like other electro-diesel locomotives, they can run on either diesel fuel or electricity. Like full dual-mode locomotives, they are designed not with an auxiliary motive source to make up for a few short gaps in the route where the main motive source cannot be used but with the intention of switching back and forth frequently. Unlike locomotives drawing power from a third rail or overhead lines, however, hybrid locomotives use onboard batteries and have the prominent advantage of being usable without waiting for infrastructure improvements. The first "hybrid" locomotives combined steam and diesel power, but today's hybrid locomotives use an onboard rechargeable energy storage system (RESS). Locomotives are relatively easy to convert to hybrid design, especially compared to automobiles.

The batteries are charged with surplus energy from the diesel engine and sometimes from regenerative braking, an energy recovery system that assists with braking the train by converting the kinetic energy of the train's forward motion into stored electricity instead of the waste heat generated by the friction of conventional braking. (Regenerative braking only works well until the train has slowed down, at which point the conventional braking system brings the train to a full halt.) Regenerative braking has been used on locomotives since the 1930s. In fact, in some Scandinavian mining communities, trains bearing ore generated more energy going downhill (when the brakes were needed for much of the trip in order to slow the heavy train) than they used, and that excess electricity was pumped into the local power grid, providing electricity for the local residents. Of particular interest today is the fact that electricity generation through regenerative braking is a carbon-neutral form of electricity generation, which helps offset the environmental impact of operating a diesel engine. Regenerative braking has also long been used in the race cars used in motor sports.

Hybrid electro-diesels typically draw their power from both a diesel engine and batteries, but some may also have the ability to draw electricity from a third rail or overhead lines, depending on the route they serve. The Canadian company Railpower began operating experimental electro-diesel hybrids in the United States in 2004, which have since been adopted by a number of railways. Railpower's hybrid design, called the Green Goat, has 90 percent lower emissions than full-diesel trains of similar payload. The Green Goat uses a six-cylinder 300-horsepower inline engine (manufactured by Caterpillar) and a bank of batteries providing an additional 1,700 horsepower. They have a top speed of 60 miles per hour. Over 50 Green Goats have been produced and sold to Canadian and U.S. companies, deployed by the BNSF Railway, the Canadian Pacific Railway, the Kansas City Southern Railway, the Modoc Rail Academy, Railserve, the Union Pacific Railroad, and the U.S. Army. BNSF has experimented with converting its Green Goat from a diesel engine to one using hydrogen fuel cells, a design similar to one used in Japan in smaller locomotives.

General Electric's GE Evolution Series of low-emissions locomotives includes a hybrid electro-diesel using sodium-electric batteries and regenerative braking. A hybrid electro-diesel using biodiesel

has also been added to the streetcar line of the city of Savannah, Georgia, and has been in operation since 2009 as part of the city's attempts to reduce environmental impacts and air pollution.

Electric Vehicle Recharging Stations

Electric vehicles (EVs) include plug-in hybrid and battery electric hybrid (BEVs) cars that use a battery to power a vehicle's motor. They include cars, buses, scooters, motorcycles, and small short-range vehicles. In the case of plug-in hybrids, drivers can use either traditional fuel for an internal combustion engine or plug the car into the electric grid.

EVs and plug-in hybrids, when powered by the battery, offer a number of benefits to the owner and the environment. EVs have no tailpipe emissions, thereby reducing the amount of greenhouse-gas emissions attributed to driving. Because the vehicles use electricity instead of petroleum-based fuel, they cost less to operate than a traditional combustion-engine-powered vehicle and have lower maintenance expenses.

Though EVs do have a carbon footprint associated with electricity production, they have less impact than traditional vehicles, especially when the grid uses wind, solar, or water to generate electricity. Engines in EVs are more efficient, converting approximately 60 percent of their electrical energy

to power, versus conventional vehicles which convert just around 20 percent of the stored energy in gasoline to power. Most models operate quietly and have competitive acceleration.

Electric Vehicle Prevalence

Because EVs have less negative impact on the environment and do not depend as much on fossil fuels as traditional vehicles, many countries have set aggressive goals for increasing the percentage of EVs on the road. Fifteen countries from around the world have joined the Electric Vehicle Initiative (EVI) to encourage the use of EVs in member countries, eight of which are among the 10 largest vehicle markets worldwide.

EVI countries claimed 180,000 electric vehicles, excluding motorcycles, buses, and heavy duty vehicles, or 0.02 percent of total passenger cars. The Electric Drive Transportation Association reports that fewer than 100,000 electric cars have been sold in the United States since 2011, which represents

just 0.13 percent of total new vehicle sales. In 2012, according to *USA Today*, automakers sold 53,172 plug-in electric vehicles and 434,498 hybrid vehicles, a total market share of 3.4 percent.

The Chinese Association of Automobile Manufacturers Association reported 12,791 sales of hybrid and electric vehicles in China, but after eliminating vehicles, such as golf cars, that are not roadworthy, the number shrinks to approximately 3,000 vehicles. In the smaller Norway market, the Nissan Leaf is the fifth-best seller among car models, but in the United States, where Nissan had planned to sell 20,000 vehicles, only 9,819 have been sold and fewer than 50,000 of the model have been purchased worldwide.

Despite EVs being slow to catch on with consumers, a market study by Pike Research estimates that by 2020, annual global sales of electric or plug-in hybrid cars will reach 3.8 million. Currently, the highest rates of EV ownership are in the United Kingdom, Germany, Japan, China, and the United States, and the use of EVs in government and corporate fleet vehicles is increasing. Some countries, such as the United States and the United Kingdom, as well as individual states, provide tax incentives to purchasers of EVs to encourage usage.

Barriers to Adoption

Consumers may eschew EVs for many reasons. Plug-ins tend to demand a premium price because of the expense of the battery, a part that usually needs to be replaced at least once. The Chevy Volt, for example, retails for over \$40,000 in the United States, and the Nissan Leaf ranges from \$28,000 to \$34,000. High-end Tesla EVs can cost between \$62,000 to \$82,000. In the United Kingdom, EVs range from \$31,000 (£20,000) to \$46,500 (£30,000).

Some consumers are reluctant to purchase EVs because of their relatively short driving range, 100 to 200 miles, between charges. According to the EVI's "Global EV Outlook" report, 75 percent of Americans surveyed were wary of the range restrictions, even though studies indicate that the average car trip in the United States is just over 9 miles, and daily travel is just over 28 miles, on average. Gasoline-powered cars can go up to 300 miles before needing to refuel, and drivers enjoy the confidence of knowing that a gasoline station will be nearby.

EV drivers have fewer options for recharging their vehicles. In the United States, there are 5,800

A Chevrolet Volt recharging in Fremont, California, in 2012. As of 2013, there were only about 5,800 public recharging stations in the United States, while there were over 167,000 gasoline stations. Batteries can be charged up to 80 percent in 30 minutes.

public recharging stations, compared to more than 167,000 gasoline stations. The United Kingdom offers approximately 200, compared to more than 9,000 gasoline stations, while Japan has nearly 2,000, compared to 38,000 gasoline stations. Many EV owners who have off-road parking have private recharging stations in their garages or driveway.

To fully recharge an EV's battery pack can take as long as eight hours, though quick charges that fill the battery to 80 percent capacity can be done in half an hour. In most countries, smart phone applications or Web sites provide searchable databases with maps to help consumers locate the nearest recharging stations. For residents of apartment or homes without off-street parking, EVs may be out of reach because it is not possible to install a recharging station at home.

Electric Vehicle Supply Equipment

Recharging stations, also known as electric vehicle supply equipment (EVSE), are categorized into Level 1, Level 2, and DC Fast Charging types. Level 1 EVSE uses 120-volt AC plugs and adds 2 to 5 miles of range for each hour the vehicle is charged. Level 2 equipment utilizes 240-volt electrical service and adds approximately 10 to 20 miles of range for each hour charged. DC Fast Charging EVSE, with 480 volts of AC input, provides 60 to 80 miles of range for each 20 minutes charged.

The company Better Place, which operates in Denmark and Israel, promotes replaceable or switchable batteries, so that drivers can go to a battery switch station and, in a matter of minutes, exchange depleted batteries for ones with a full charge. One challenge for users and manufacturers of EVSE can be opposing standards for plugs and receptacles. SAE International provides the Combined Charging Systems protocol, adopted by German and U.S. automobile companies, while CHAdeMO offers a competing set, adopted by Japanese car manufacturers. While all North American cars and chargers follow SAE's protocol, the incompatible standards can be particularly vexing to European drivers, who drive more frequently across national borders.

Public recharging stations can be paid for by companies wanting to contribute to environmental initiatives in the community. These might be available for employee use to encourage employees to drive environmentally responsible cars, or they might be available to customers as an incentive

for frequenting the business. In the United States, for example, Walgreens is the largest retail host of EVSE, and as of 2012, the company planned to install 800 at their locations nationwide. Some companies, such as public garages, might provide recharging station access for a fee, allowing it to become a revenue generator for the business.

Initial costs for EVSE include the station itself, as well as installation by a professional electrician. Long-term costs include maintenance and the electricity attributed to the charging. In peak times, this can be a concern. Many national and state governments who want to promote the acceptance of EVs provide grants or subsidies for EVSE installation. In Illinois, homeowners, businesses, and community colleges can receive grants for half of the EVSE installation expenses as part of the 2900 Illinois Jobs Now! Act, which earmarked \$10 million for EV infrastructure.

Nationwide, the American Recovery and Reinvestment Act (ARRA) provided a federal stimulus grant of \$114.8 million, matched by private donations for a total of \$230 million, administered by the U.S. Department of Energy for the EV Project, managed by the firm ECOTotality. The EV Project is active in nine states and the District of Columbia with a goal to promote an EV infrastructure. Fifteen thousand charging stations were available to commercial and residential applicants. As of March 2013, all available units had been distributed, exceeding anticipated public demand.

Public charging stations use Level 2 or DC fast charging. If public charging stations are located conveniently with some density, consumers will likely feel more comfortable with the driving range of EVs. With more EVs on the road, emissions are decreased. Additionally, public stations can allow drivers of plug-in EVs to recharge and use the battery rather than the gasoline engine, further reducing harmful emissions into the environment.

Some areas, such as Sonoma County in California, have extensive guidelines and a permitting process, including a site plan for placement of an initial EVSE infrastructure. Other areas install recharging stations on a more ad hoc basis. Sonoma County outlines three considerations for potential hosts of public recharging stations, which are relevant in all areas.

First, the site location should be conveniently located and near heavy-traffic corridors, and the

site should have adequate electric service, be out of flood zones, and away from water. Second, the host should review the user base of the potential EVSE, considering the peak hours, the walking distances to attractions and retail establishments, and perceptions of safety. The third consideration is the parking location. In this area, the host should consider the placement of the chargers, the signage needs, the available light, placement of cables, the demand on the electric system of the building or structure, and accessibility for mobility impaired users.

For those who install private or public EVSE, as well as for communities as a whole, another concern of EVs is the strain on the electrical power grid. Research for Mueller, Texas, a neighborhood with the highest concentration of Chevy Volts in the United States, found that most residents plug in their cars when they get home from work at the end of the day, the same time they turn on the television and computer, adjust climate controls, and use kitchen appliances. Such high concurrent usage in American cities, where the grid is relatively well-developed, could still potentially cause blown circuits, but in countries such as France, where the electric grid has little flexibility at peak periods, representatives of the French power company, RTE, fear that heavy use of chargers at peak hours could cause power surges and possibly disruptions in service.

Companies are researching smart charging mechanisms to incorporate into EVSE so that when plugged in, the EVSE will detect the best time to charge based on the grid demands. Other researchers are testing how electric vehicles might store excess capacity in the grid during off-peak usage in their batteries and sell it back to the power companies.

EVSE Vendors

A number of manufacturers produce recharging stations. The company 350Green manages site selection, engineering, construction, and marketing of recharging stations, and works with municipal and corporate partners, including Walgreens. PEP Stations provides recharging stations for public EVSE hosts that can accept major credit cards.

In addition to managing the EV Project, ECOTALITY produces Blink recharging stations, notable for their sleek style and flat screens to process transactions and display advertisements. A long-time

partner with automobile manufacturers, Bosch also supplies a line of residential and commercial recharging stations in the United States, Canada, Europe, and Asia. A division of Control Module Inc., EVSE LLC offers portable recharging stations for valet parking and service bays.

Future Concerns

For electric vehicles to gain in popularity, a number of agents must work in concert. Governments must provide incentives and assist in the development of an infrastructure. Electric companies must find ways to work with EV users to diminish strain on the grid. Car manufacturers must produce competitive and interesting models of EVs. Consumers and corporate purchasing agents must be willing to purchase electric vehicles.

Governments throughout the world are working with manufacturers to install recharging stations and develop a strong infrastructure for electric vehicles. However, it seems the other elements are not yet coalescing into momentum to substantially increase the number of EVs on the road. Without consumer demand, manufacturers are focusing production on high-mileage traditional vehicles or plug-in hybrids.

Nissan Motor Company, one of the biggest supporters of EVs among car manufactures, announced that it was shifting its strategic focus to plug-in hybrids, and Toyota Motors is developing hydrogen-powered fuel-cell technology instead of manufacturing battery-powered electric cars. The current push for expanding the infrastructure of recharging stations could mark the beginning of the era of electric vehicles, or it may eventually stand as a monument to another failed effort to wean drivers off of fossil fuels.

Electric Vehicles

When President Barack Obama, in his 2011 State of the Union address, set a goal of putting 1 million all-electric vehicles on America's roadways by 2015 (the first country that would achieve that milestone), comparisons were inevitably drawn to President John F. Kennedy's bold clarion call nearly a half century earlier to land a man safely on the moon.

As with Kennedy's electrifying challenge, Obama's call for national support for electric vehicles created an urgency to realize a broad vision in which technology and science would achieve a landmark that would, in turn, become a manifestation of American pride and achievement. As part of his challenge, Obama pledged \$2.4 billion to research and development of electric vehicles as well as large tax credits to vehicle buyers.

Much as Kennedy's challenge appeared at the time a pipe dream, Obama's vision was almost immediately dismissed as unattainable—although

there existed a promising market for hybrid cars (cars that use gas as well as electricity), all-electric vehicles had accounted for fewer than 1 percent of cars sold that year; even hybrids fared only slightly better (roughly 3 percent). Industry analysts cautiously projected perhaps by 2020 the million car mark might be achieved. But like Kennedy's challenge, Obama's call is perhaps more doable than it might at first appear, more calculated, and far more modest than it might seem. After all, 1.6 million electric vehicles had been sold in the six years before the State of the Union address, of which just under a half million were still in use, and if the vehicles could maintain a modest 1.7 percent of the overall sales of lighter vehicles (which average 15 million units per year in the age of the downsized automobiles and steadily escalating fuel prices), the million vehicles on America's roads was eminently attainable at least near Obama's target year.

In fact, it might be the greater challenge to overcome public misperceptions about the vehicles' range and expense and the usual uneasiness of consumers being introduced to any radically new kind of technology (similar resistance met by personal computers less than a generation earlier). Strident advocates of electric vehicle technology, in fact, considered Obama's national goal, if anything, too timid (European automotive analysts project that by 2025 all vehicles sold in Europe will be electric or minimally hybrid cars). These vocal proponents argue that America must embrace electric vehicles sooner rather than later and, in turn, move decisively toward asserting energy independence at least in the transportation sector and, in so doing, start to bring under control the greenhouse gas emissions from conventional gasoline engines, levels that had, over the last decade, reached alarming, unprecedented levels.

History

Although electric vehicle development appears at the cutting edge of contemporary technologies (in 2010 alone there was a 60 percent spike in the number of patents issued for electric vehicle components), electric vehicle development actually predates hydrocarbon vehicles by nearly half a century. Prototypes were developed beginning in the 1820s in a variety of laboratory workshops in Europe (historians cannot agree on a single clear line of credit for the design). By the early 20th century, in

addition to electric railway systems, electric cars in both Europe and America were ubiquitous, and unlike the contemporary horseless carriages with their internal combustion drive, electric vehicles were valued not only for their speed (they averaged about 20 mph) but also for their clean comfort, their quiet ride, and their easy drivability (in fact, they were often marketed as “women friendly”). Of course, given the relatively brief life of the battery cells at the time, electric vehicles were found most often in cities, and given the few power plants and the general thinness of America’s energy grid, electric vehicles were mostly found in the industrial Northeast corridor.

With the turn of the century oil boom (massive reserves tapped in Texas, Oklahoma, and California) and the national initiative to build an interstate highway system in the century’s first two decades, internal combustion cars (and long-distance driving) became the craze, and the electric vehicle faded from the national consciousness, save for a brief interest during the fuel reserve crises of World War II. In technology-enriched postwar America, innovations in electric vehicles were realized in train and subway systems, golf carts, boats, wheelchairs, and mail trucks, as well as military vehicles and submarines. Perhaps the most notable electric vehicles of the era were the three lunar rovers left behind on the moon by Apollo astronauts. Although the Big Three car companies had divisions investigating electric vehicles as early as the mid-1950s, there was little progress as there was little urgency. That would change dramatically in the mid-1970s when America faced the twin threats of a massive energy crunch from oil dependency on politically unreliable foreign markets and the growing scientific data on the short- and long-term damage hydrocarbon burning caused the atmosphere.

After a brief national embrace during the Clinton boom years of spacious utility vehicles with poor gas efficiency, the global economic recessions of the early 2000s returned attention to the promise of electric vehicles as environmentally aware consumers called for reliable and affordable models. Promoted initially as ideal for short-distance drives, electric vehicles (and the next generation hybrids) quickly gained national attention. By the mid-2000s, numerous corporations who relied on delivery systems (department stores, furniture stores, hotel chains, food producers, package

delivery organizations) had embraced electric vehicle technology. Rental car agencies announced plans to introduce electric vehicles as an option. In the aftermath of Obama’s rallying call for an embrace of electric vehicle technology, General Electric announced its own ambitious program to buy 25,000 electric vehicles for its global fleet, to date the largest single corporation investment in electric vehicle technology.

Types

An electric vehicle is similar to a conventional fossil-fuel burning vehicle save that it is powered by a rack of rechargeable batteries (manuals for the conversion of conventional cars into electric vehicles by amateur car enthusiasts are a booming business). Conversions involve removing from the donor car the engine, the gas tank, the cumbersome exhaust system (electric vehicles are fume free) and installing a complex of lead-acid batteries (usually a dozen 12-volt units); a controller to direct the surges in electricity; and the electric motor itself. There are three types of electric vehicles: (1) those (such as electric train systems) directly powered by actual attachment to a remote external power sources, most often by overhead or underground wiring; (2) plug-in vehicles powered by electricity stored from external sources accessed through conventional wall sockets in rechargeable electric storage systems (the process takes on average six hours); and (3) vehicles actually powered by on-board electric generators or fuel cells.

Trendy hybrid vehicles have found a sales niche, such as the popular Toyota Prius (the first mass-produced electric vehicle in the United States with more than 3 million units sold since its introduction in 2001), the Dodge Dart, the Ford Fusion, and the Volkswagen Jetta, vehicles that use a combination of gasoline and electricity and offer a greater driving range than conventional electric vehicles yet do considerably less damage to the environment.

Benefits and Drawbacks

Certainly the argument in favor of developing electric vehicle technology that most often becomes an applause line for politicians is its promise to help America achieve energy independence. Electricity, after all, is a domestic product. Projections indicate that wide embrace of electric vehicles could reduce foreign oil dependency by as much as 60

percent inside a decade. Of course, it is not that simple. Critics are quick to point out that more than three-quarters of the power plants crucial to providing electric vehicles with their charge, in fact, burn fossil fuels (natural gas and coal). So, they argue, electric cars are in fact burning fossil fuel the same as conventional cars. Advocates counter that such crucial energy production can, and will, ultimately be shifted to renewable energy sources such as nuclear, wind, hydro, and solar power and that given the clean efficiency of the electric engine, even when the energy source is provided by a fossil-fuel power plant, carbon dioxide emissions overall are still cut substantially, nearly in half.

Scientists point out that a far more important advantage of electric vehicles comes from their energy efficiency. Ninety percent of the energy produced by an electric vehicle system is converted to actual work; electric engines do not burn fuel when they idle, and the vehicles have no tail-pipe emission by-product. Climatologists argue that carbon dioxide emissions in the first decade of the 21st century have already reached levels that, a scant generation ago, were considered apocalyptic in their implications. Although other factors have contributed to greenhouse gas effects (deforestation, for instance, and massive power plants), vehicular transportation is responsible for close to 80 percent of emissions. In addition, because they are virtually noiseless, electric vehicles in heavily concentrated urban areas would significantly reduce the aggressive levels of noise pollution, which psychologists have linked to high stress levels, depression, and insomnia.

In addition to environmental impact and energy efficiency, electricity is simply cheaper than gasoline. At 2013 gas prices, a cross-country trip from Washington, D.C., to San Francisco, about 2,500 miles, would cost a little over \$350 in gas; electricity would cost about one-sixth of that (although critics are quick to point out that recharging stops would inevitably impact driving time and consequently expenses). Buying electricity for electric vehicles would be like paying just under 75 cents for a gallon of gas.

Ultimately, proponents of electric vehicles extol the most immediate benefit: the ride itself. The vehicles offer an unparalleled quiet riding environment, unstrained acceleration (although the short quick jump often required for passing can present

problems); and smoother operation on uneven surfaces, tight curves, and wide turns. Given the relatively simple engine construction, maintenance is far easier and engine breakdowns are far less frequent, although loss of power from a tapped battery set is a concern. Repair work is significantly less worrisome, although finding mechanics competent, or even willing, to work on the vehicles can pose a problem.

There are other problems. The current lead-acid battery is bulky and heavy and has a relatively short life—they start to degrade on average after just two years, which means owners could face multiple replacements of battery packs for a single car. Replacing the battery system is prohibitively expensive, as a battery pack averages \$2,200. Advocates, however, quickly point to the sufficiency of the lead-acid battery. If developers of the next generation of electric vehicles are already working on extending the range of the batteries to make electric vehicles long-distance competent, AAA data indicates that currently the average drive distance for most errands is typically about 9 miles, well within the range of lead acid battery technology.

U.S. Department of Transportation data suggests that 80 percent of vehicle owners in America drive, on average, 50 miles or fewer a day. The storage capacity of lead-acid batteries permits between 50 and 100 miles between recharging, and recharging is a matter of plugging in the engine to an external power outlet, a process that can conveniently be done overnight or during the workday with the advent over the last decade of businesses and even cities providing a network of accessible recharging stations (most major European cities already have them or are constructing them). That means that electric vehicles and lead-acid batteries are currently able to meet the demands of ordinary day-to-day driving needs.

By comparison, however, a tank of gas can give a vehicle owner more than twice that range. Electric vehicle owners often fret over losing the vehicle's charge far from a recharging station or far from home (the condition has been termed *range anxiety*). Because even the most diligent owners inevitably neglect basic recharging responsibilities and because recharging is time consuming, the public perception of all-electric vehicles, inevitably, is that they are impractical, good only for local driving, suburban commutes, and limited weekend and

evening errands. They are widely perceived to be a useful second car, a way for upper-income advocates of trendy green causes to endorse electric vehicles without actually depending on them.

The cars become, in turn, a kind of status symbol or a very public political statement, the car itself more an activist statement than an actual working vehicle. Critics of the government-spurred research glut into marketable electric vehicles point out that urban centers would be far better served by developing fuel-free transportation systems—particularly creating pedestrian incentives, building state of the art biking paths, or investing in all-electric public transportation systems.

Future Developments

Developing long-distance range capability is the primary goal of electric vehicle technology. That hinges on evolving a better battery system. Most promising is the lithium-ion (li-on) battery that

is far lighter than lead acid type, can be fully recharged in under 20 minutes, and can hold the charge far longer, thus promising to extend the range of electric vehicles up to the standard range of a full tank of gas, roughly 300 miles. In the early 2000s, however, lithium-ion battery technology, although central to consumer electronics for years, was considered by transportation industry analysts more than decade off for widespread vehicle use, unworkable for passenger car use. Then the car industry was electrified in 2008 when a modest start-up company in California, Tesla (named for the pioneering electrical engineer Nikola Tesla), unveiled its Roadster, a snazzy two-seat convertible with a lithium-ion battery system. It catapulted the tiny company into global celebrity, and, despite its \$100,000 price tag, the Roadster was a market sensation.

Other models have found similar success, most notably the Nissan LEAF. In late 2013, scientists at

The all-electric Tesla Roadster sells for around \$100,000 and can be recharged from a household electrical outlet if needed. All-electric vehicles made up less than 1 percent of all cars sold in the United States in 2011, while hybrids captured about 3 percent of the market. While electric car sales remain modest, predictions for their use range as high as 8 million vehicles worldwide by 2025.

Germany's Center for Solar Energy and Hydrogen Research announced they had successfully tested a li-on battery that would be capable of providing a vehicle a working charge for more than 25 years.

Although sales of electric vehicles currently lag behind industry expectations and far below the inspirational rhetoric of politicians, electric vehicles are poised to become by necessity a staple in the global car market given the steadily escalating cost of fossil fuel and the growing apprehensions over long-term damage to the environment. Plug-ins, hybrids, and even the high-maintenance all-electric vehicles will claim a growing share of the world vehicle traffic, by some projections more than 8 million on the world's roads by 2025.

Electronic Route Guidance Systems

In the 1960s, the U.S. government endorsed electronic route guidance systems (ERGS) as the forerunner of a more comprehensive research and development program utilizing intelligent transportation system (ITS). A system integrating advanced technologies such as communication engineering, information theory, and navigation principles, ITS helps make transportation systems more reliable and efficient. Since the 1990s, the ITS field has expanded rapidly and provided traffic advisory information and route guidance to motorists as traffic congestion continues to hamstring modern societies across the world.

Types of Systems

In-vehicle navigation and route guidance systems come with dual purposes—they can be used for navigation and/or following a route. The basic navigation system features a map with the location of a vehicle so that drivers can follow a chosen route to their destinations while route guidance systems provide drivers with specific routing instructions. Systems can also be classified based on their communications with the outside world; they are considered to be autonomous if they continuously self-navigate with no active external communication links and use dead reckoning with radio trilateration (passive reception) and/or map matching. Autonomous systems may also give static route guidance based entirely on internally stored historic map information.

Proximity systems are not considered autonomous, because they need to communicate with a roadside beacon for continuous navigation. Other more sophisticated versions of proximity systems include a one-way communication link to the vehicle from a control center creating the conditions for semi-dynamic route guidance and hazard warning besides static route guidance. This feature allows recent changes in historic road networks to be updated and provides information about prevailing traffic and emergency conditions in the network through area wide or local data radio broadcasting.

Systems with two-way communications or integrated systems create the opportunity for dynamic real-time route guidance for the individual driver, providing responsive routing to the driver's

destination while allowing the driver to make emergency calls. It provides for central monitoring and the command of individual vehicles necessary for traffic and fleet management.

Origins

The origins of electronic route guidance systems can be traced to the mid-1960s when Alan Stephenson Boyd headed a task force that recommended establishing a Department of Transportation to President Lyndon B. Johnson. The new Department of Transportation would include the Federal Aviation Agency, the Bureau of Public Roads, the Coast Guard, the Saint Lawrence Seaway Development Corporation, the Great Lakes Pilotage Association, the Car Service Division of the Interstate Commerce Commission, the subsidy function of the Civil Aeronautics Board, and the Panama Canal.

On March 6, 1966, after he modified the recommendations that the Boyd task force made, President Johnson sent Congress a recommendation urging it to establish a new Department of Transportation with the task of coordinating and managing transportation programs, providing leadership to resolve transportation problems, and to develop national transportation policies and programs.

President Johnson's argument was that America's safety, economic health, and national defense depended on the strong foundation of a modern transportation system, and he acknowledged that although the American transportation system ranked as the best in the world, its operations wasted lives and resources. As President Johnson said, "America today lacks a coordinated transportation system that permits travelers and goods to move conveniently and efficiently from one means of transportation to another, using the best characteristics of each."

On October 15, 1966, President Johnson signed the Department of Transportation enabling act after compromising with Congress and accepting an altered version of his original bill. The newly created U.S. Department of Transportation, Bureau of Public Roads played a pivotal role in creating early electronic route guidance systems.

Early Electronic Route Guidance Systems

During the 1960s and 1970s, the probability of improved driver routing information and controlling and directing the flow of traffic motivated the federal government and private industry to

introduce several experimental in-vehicle route guidance systems. These systems did not provide in-vehicle navigation capability but rather were integrated systems that used interactions with roadside units called proximity beacons to fix vehicle positions and provide ongoing route guidance. During the 1960s, two experimental guidance systems appeared. In the United States, General Motors Corporation developed the Driver Aid Information and Routing System (DAIR), which used different arrangements of magnets in the roadway to identify specific locations throughout the routing network and CB radio for communications.

The Office of Research and Development, Bureau of Public Roads, as part of the U.S. Department of Transportation, developed the second experimental system of the 1960s using electronic equipment in participating vehicles and at intersections to guide motorists, known as an electronic route guidance system. The program focused on the destination of the motorist, with the driver entering a code word as a symbol of his or her destination into the system. As the vehicle approached each intersection equipped with instruments, the instruments transmitted the destination code to the roadside where a stored program decoded it. The program transmitted a routing instruction back to the vehicle and displayed the instruction with a symbol or word message containing the maneuvers the driver should make at the intersection or interchange. In the late 1960s, the government canceled the program because of the projected high cost of the required infrastructure.

During the 1970s, industries developed an array of roadside based systems, including Philco-Ford, a destination coding system, and techniques for solving routing problems. An early map matching system, Automatic Route Control System (ARCS), first appeared in 1971 on a newspaper delivery route, using a differential odometer and a map matching algorithm to correlate measured positions with that on a digitally encoded route map. Few of these systems survived beyond the experimental stages because most of them required an extensive roadside infrastructure to operate and were only cost effective in congested urban areas.

1980s and 1990s Systems

In the 1980s, the major automobile manufacturers and many electronics companies developed a new generation of ERGS with the goal of marketing them

as showroom options or aftermarket accessories. These systems combined several different navigation technologies to form autonomous or self-contained in-vehicle navigation systems mostly based on electronic maps of some kind and were limited by map coverage, although not necessarily map matching. Some of the systems provided drivers with route guidance information to their destinations. Unlike infrastructure-based systems, the user bore the entire cost of ERGS systems. Characteristics of some typical ERGS systems included a range of technologies, performance strengths and weaknesses, and differences in cost and potential marketability.

Contrasted with ERGS systems, map matching systems depended on the supply of accurate maps, which were not always readily available to be digitized, to generate the necessary map database. The digitizing process could be expensive and time consuming and since the road network often changed over time, keeping the map database current was difficult. The various map matching systems reflected the three standard methods of storing map information: photographic, digital image, and digital encoded. Digital encoding, the most sophisticated method, involved digitally encoding the map as a set of intermodal vectors defining each roadway and intersection. The early Honda system used photographic storage, the least sophisticated method, which required the user to slip a transparent map overlay over the CRT. Chrysler used the video image method.

In the 1970s, Bosch/Blaupunkt and Siemens jointly developed the ALI-SCOUT navigation system, which combined a dead reckoning navigator—magnetic compass and differential odometer—with two infrared communicators between a vehicle and the roadside. Rather than storing a large map in the vehicle, the navigation system fed a digitally encoded map covering the immediate surrounding area into each vehicle as it passed a beacon. It also included recommendations about traffic conditions.

Founded in 1983 in California, Etak Inc. pioneered commercialized automotive navigation systems and digital mapping technologies that became standard in vehicles in later decades. In 1985, Etak introduced the Navigator, its flagship system, which is the ancestor of many modern GPS-based automotive navigation systems.

The first commercially available automotive navigation system using map matching technology,

the Etak Navigator used a flux gate magnetic compass and a differential odometer for dead reckoning information and stored the digital map data on magnetic tape. At the start of the trip, the driver entered origin-to-destination information and the system continuously tracked the location of the vehicle and its surroundings on a CRT map display. A stationary arrowhead in the center of the CRT screen pinpointed the vehicle position and a star marked the vehicle's destination on the map. As the vehicle traveled along, the map moved with the arrowhead so that the map always showed the same view of the roadway as the driver saw ahead of the vehicle. Etak claimed navigation accuracy of better than 100 feet. General Motors Corporation bought the North American rights to Etak technology, although other companies in America and abroad developed similar systems. The CD ROM's capacity to store massive map databases, including a digital map of every highway and street in the United States and Canada, forecast a promising future for Etak technology.

Global Positioning System Satellites

Four generations of GPS satellites have operated since 1940, when the idea for a global positioning/navigator system was first introduced. The U.S. Air Force developed global positioning technology, and then civilian companies gradually adapted it to commercial use. Operated by the 50th Space Wing of the Air Force, the Global Positioning System (GPS) satellite network provides target information to military forces around the world, but it also guides individual civilian vehicles on their daily journeys.

The GPS Space part of the system features six orbital sectors that require at least four satellites in each to operate. The control system has monitoring stations in Hawai'i, Kwajalein, Ascension Island, Diego Garcia, and Colorado Springs and three ground antennas at Ascension Island, Diego Garcia, and Kwajalein. A Master Control station is located at Schriever AFB in Colorado. The NAVSTAR GPS Joint Program Office at the Space and Missile Systems Center at the Los Angeles Air Force Base in California manages the NAVSTAR Global Positioning System.

NAVSTAR

In 1973, the Pentagon proposed a global positioning satellite system eventually called NAVSTAR,

in response to the military necessity of delivering weapons on target and reversing the growth of navigation systems in the U.S. military. The creators of NAVSTAR designed the system to operate with at least 24 satellites in orbit, and the Air Force launched the first generation of NAVSTAR satellites in 1978. The U.S. Department of Defense immediately recognized the significance of GPS to civilians around the world, and in 1989, the first full-fledged GPS satellites were launched, designed to operate 14 days without any input from the control systems on the ground. Between 1989 and 1990, the Air Force launched nine more satellites.

In June 1993, the last of the 24 GPS satellites went into orbit, finishing a satellite network that could provide position data to locate a vehicle within a 98-foot range anywhere on earth. The satellites, which transmit timing signals and position data, carry as many as four cesium and rubidium atomic clocks that the ground station in Colorado periodically updates. A GPS receiver, which may be a small, hand-held instrument, decodes timing signals from several of the satellites, translating the arrival times in terms of latitude, longitude, and altitude with a margin of error that can range as small as 33 feet. The satellites orbit about 11,000 miles above the Earth with orbit periods of about 10 hours.

In 2000, President Bill Clinton advanced civilian uses of the GPS system when he ordered the Pentagon to stop manipulating factors, including orbital data and the frequency of the satellite's clock, in a policy called "selective availability," which gave the military optimum advantages. After the terrorist attacks on New York City's World Trade Center and on the Pentagon in Washington, D.C., on September 11, 2001, civilians thought that the Pentagon would reinstate "selective availability," but the Interagency GPS Executive Board reported no change. Following the advice of the Department of Defense, President George W. Bush in 2007 decreed that the NAVSTAR III generation would not feature selective availability at all.

The Air Force has improved NAVSTAR satellites over the generations, and the current versions have an estimated life of 12 years and faster processing power. The Air Force has launched three NAVSTAR 2-F systems, with the latest one in 2012. According to manufacturer Lockheed Martin, the next GPS generation called GPS III will be three times more accurate and will come equipped with

an "antijam" security system. The Air Force could order at least 32 of the Lockheed Martin GPSIII satellites, which are scheduled to launch in 2014–15 and are expected to last for 15 years or more.

Other countries, including Russia and several in Europe, have built similar systems to GPS for civilian and military use, and NAVSTAR is working to meet the competition by improving the accuracy of its system. According to the Federal Aviation Administration, current GPS systems are accurate to within 40 feet and military systems pinpoint within a few inches.

Conclusion

The vision of researchers and entrepreneurs for the future of ERGS includes expanded and increasingly sophisticated hardware and software for static and dynamic systems. Plans include a highway transportation subsystem that focuses on the driver as an integral part of the system but will enhance the driver's performance by removing much of the route responsibility and focusing more attention on the driver's primary task of controlling the vehicle. Adding central control facilities and communications links to intersections may also permit more uniform distribution of traffic over the highway network.

Emergency Response Systems

Naturally occurring and human-made emergencies occur every day on roadways. Emergencies on roadways may be caused by multiple automobile accidents, fires, earthquakes, landslides, radiation release, flooding, snow, ice, and chemical spills. The impacts of these events may be limited to a road intersection or affect large sections of a road network within the surrounding region. Emergency response systems provide a mechanism for emergency services to receive notification of incidents, allocate and prioritize resources, and respond to emergencies.

Emergency response systems were developed to facilitate notification and assist emergency response personnel when responding to emergencies or crises. Some of these systems are centrally monitored and provide a mechanism for emergency managers and organizations to manage and allocate resources during emergency or crisis responses. Automobiles or highways may be equipped with automated sensors that notify emergency response systems when and where an incident has occurred.

Over the years, emergency response systems have transitioned from analog phone communications to mobile and computer-based phones and sensors. As urban populations continue to increase, road networks are becoming more and more congested, leading to increased numbers of emergencies. Technologies and methods for responding to emergencies have improved as a result. Several types of emergency response systems exist on roads, including hazardous materials response systems and automobile response systems for vehicle breakdowns and accidents. Notifications for these systems may occur through the 911 Emergency Response System, intelligent transportation systems, or automated notification systems. Emergency services, such as police, fire, and ambulance, support the response systems, depending on the type of event. During response to an incident site, agencies can use the Incident Command System as a framework for managing and coordinating resources from various agencies.

Resources

Many resources are used in support of emergency response systems. Real-time data, such

as aggregated cell phone location data and road conditions, provide up-to-date information on where citizens are located and where authorities may need to respond. Remotely sensed data, such as aerial and satellite imagery and closed circuit television (CCTV), provide planners with visual information that can be integrated into emergency response planning. For example, recent satellite imagery may provide information on a new subdivision or retail establishment that was built in an incident area. CCTV is often used to determine which citizens are responding to instructions from emergency managers.

Often, geographic information systems (GIS) are used to assist with planning and allocation of resources. Crisis resources are often geographically dispersed, including police, fire, emergency medical services (EMS), hazardous materials (HAZMAT) response, and airborne assets (helicopter, plane, and unmanned aerial systems). GIS provides a toolset that can track assets and their locations and provide estimated arrival times to an incident. GIS is frequently used to analyze data to support emergency response. When an incident is identified, GIS provides tools to identify at-risk areas that emergency response personnel need to prioritize for notification and allocation of resources. GIS enables emergency response personnel to analyze citizens' locations, identify the status of the road network, and determine the optimal evacuation route that minimizes risk to citizens as they evacuate. With proper coordination from authorities, GIS data and analysis can be shared among agencies on desktop computers, laptops, tablets, and mobile phones.

It is imperative that planning for access to resources occurs prior to an incident. Coordination between adjacent jurisdictions for data sharing is just as important as mutual aid support. Agencies should ensure that in emergencies, data and analysis can be shared with adjacent jurisdictions without contract violations (for example, sharing remotely sensed imagery with other agencies to support their planning and response). Joint exercises and training for support personnel that involves personnel from other jurisdictions can assist with identifying problems that involve both jurisdictions, prior to an incident occurring. Joint exercises and training also assist with building trust and minimizing conflicts during an event.

Iowa Army Guardsmen assisted in rescuing the driver of this disabled car during a severe snowstorm in Iowa City, Iowa, February 1, 2011. Emergency response systems may eventually be able to make use of both vehicle-to-vehicle (V2V) and vehicle-to-infrastructure (V2I) communications. Data would be provided by each vehicle within the network of wirelessly connected automobiles to the transportation network, allowing other drivers to change routes and giving emergency responders advance details about incidents.

Hazardous Materials Response Systems

Emergency response systems on roadways include systems for responding to hazardous materials (HAZMAT) spills, accidents, and vehicle breakdowns. Planning and response for each of these events may involve federal, state, and local agencies and resources. Various chemicals, including toxic waste, radioactive materials, gasoline, oils, and gases are transported on highways every day. Occasionally, a transport vehicle is involved in an accident or has a leak or spill. Specially trained personnel are needed during response to HAZMAT incidents to identify the material and the impact to the surrounding area. HAZMAT-trained personnel work in coordination with other agencies to secure the site and notify any personnel in the danger zone where to evacuate. Emergency response systems enable planners to identify the footprint of the danger zone, who is affected, and what additional resources are needed to safely evacuate the area and clean up the spill.

Manual and Automated Notification Systems

Traditional emergency notification involved an individual calling 911 and reaching a 911 operator. Universal emergency response systems, such as 911, were initially developed with land-line communication and eventually adapted to support mobile phones. Current 911 calls can be geolocated to a mobile phone tower or an area within the mobile phone tower footprint. To improve support to mobile phone customers during emergencies, mobile phone companies and the Federal Communications Commission are working to establish “text-to-911” and enhanced geolocation capabilities that provide the latitude and longitude of mobile calls.

During the past two decades, automobiles have added sensor technologies that automatically detect when a vehicle is involved in an accident (for example, when the automobile’s air bags are deployed or the vehicle is in a collision). Automated

emergency notification systems, such as OnStar (United States) or eCall (European Union), relay messages to emergency services through automated and manual methods. For example, with OnStar, when a vehicle is involved in an accident, an OnStar-trained adviser communicates with the driver and passengers. If assistance is requested or there is no answer, the adviser sends a request to 911. The OnStar system provides the adviser with the vehicle's global positioning system (GPS) location, which is shared with emergency personnel. The vehicle also transmits direction and number of impacts, rollover status, and maximum velocity at impact. OnStar advisers share this information with first responders prior to their arrival, providing them with a measure of the severity of the accident. These systems also offer methods to manually request assistance or share information during a disaster or emergency.

The future of emergency response systems includes vehicle-to-vehicle (V2V) and vehicle-to-infrastructure (V2I) communications. Automobiles, enabled with vehicle-to-vehicle communications transfer and receive information from other vehicles, whereas automobiles enabled with vehicle-to-infrastructure communications transfer and receive information from roadside units, Wi-Fi, mobile phone towers, or satellites.

Wireless access in vehicular environments (WAVE) includes V2I and V2V communications. As WAVE is implemented, each vehicle within the network of wirelessly connected automobiles provides data to the transportation network (vehicle location, speed, etc.). This data enables other vehicles to change routes due to congestion, vehicle accidents, and other hazards along a section of highway. WAVE also provides additional information to emergency response personnel, such as the severity of the incident, number of vehicles involved, and the appropriate resources to use in the response (for example, fire, EMS, police, and HAZMAT).

The Incident Command System

The Incident Command System (ICS), which is a component of the U.S. National Incident Management System (NIMS), is an emergency response system that integrates equipment, personnel, facilities, communications, and procedures in a common organizational structure. ICS is a standardized system that is used at the site of an

incident and supports all types of hazards. During a response, ICS provides a hierarchical, top-down framework that enhances coordination between different jurisdictions and agencies.

The incident commander is responsible for the incident and is supported by section chiefs. The makeup of the sections is dictated by the type, duration, and scale of the incident. Section chiefs include but are not limited to operations, logistics, plans, and finance. The incident commander may also be supported by a public information officer and a safety officer. ICS provides a standard process for planning and managing resources. This ensures that when local agencies are overwhelmed or under-resourced for an incident, state and federal agencies can provide additional resources as needed to support local authorities.

Regional Emergency Response Systems

Similar to some systems used in military operations, regional emergency response systems such as Operational Situational Preparedness for Responding to Emergency (OSPRED) and Regional Integrated Transportation Information System (RITIS) provide a common operational picture (COP) of transportation networks in metropolitan areas. These systems are tailored to support the needs of multiple agencies (for example, HAZMAT teams, transportation departments, first responders, and others) within a transportation region.

OSPRED is an Internet-based map developed for the Maryland Emergency Management Agency. OSPRED provides situational awareness for numerous types of events, including floods, power outages, open shelters, hurricane tracks, weather watches and warnings to police and fire stations. Real-time data include weather radar, CCTV, traffic conditions (speed, congestion, incidents, and active restrictions). Information is shared through an open standard with the National Capital Region.

RITIS is similar to OSPRED; however, RITIS provides, fuses, and disseminates information (traffic, events, parking, weather, signals, transit, and computer-aided dispatch) from Delaware, Maryland, Pennsylvania, Virginia, Washington, D.C., and West Virginia. Numerous federal users (U.S. Secret Service, U.S. Capitol and Park Police, Federal Emergency Management Agency, U.S. Army and Air Force, Northern Command, and the National Security Agency) use RITIS.

Emergency Response Systems Coordination

The importance of emergency response systems is readily apparent during a large-scale natural or technological disaster. However, a lack of coordination and planning prior to an incident can result in communication challenges, lack of information sharing, and failed response from multiple agencies. For example, are data formats compatible and can data be readily shared with other agencies or jurisdictions? Do other agencies have people who are properly trained to use the data, software, or resources needed during an incident? Prior coordination, collaborative training, and exercises often identify challenges emergency planners and decision makers may face during a real-world event.

Social Media

Social media such as Twitter and Facebook have been increasingly used by emergency operations centers to increase awareness in many regions, especially urban and suburban communities. In conjunction with other notification networks, such as radio, TV, and wireless emergency alerts (WEA), social media provide an alternative means of informing the public and news media of events in a region.

Emergency response systems provide enhanced situational awareness to citizens and emergency response personnel. Additional research on emergency response systems, including the continued integration of geographic information systems and multiple methods of communication (for example, social media, radio, TV, Internet, and WEA), will enhance coordination and response to emergency incidents occurring along transportation networks. Although OSPREY and RITIS provide enhanced awareness of road networks, they lack situational awareness of rail corridors within the regions of concern. Road networks are often severely impacted by emergencies along rail networks, either directly or indirectly. The addition of rail transportation networks to these systems would enhance situational awareness of cargo and passenger transport within these regions and provide planners with insight into possible impacts to transportation networks during an emergency.

Emergency Transportation Planning and Operations

There is a strong need for emergency transportation policies and oversight from the federal government. Over 400 tropical storms, hurricanes, tornadoes, acts of terrorism, and accidents involving hazardous material occur each year that require emergency response and may even require the evacuation of the public. These, in addition to other extreme weather, wildfires, multivehicle crashes, and potential security threats, require the United States to be prepared for anything and everything. Responders must reach the scene, victims must evacuate the danger zone, and clearance and recovery resources must arrive on time.

The U.S. Department of Transportation's Federal Highway Administration (FHWA) oversees the Emergency Transportation Operations (ETO) department within the Office of Operation. This program maintains policies and procedures for disasters, traffic planning for special events, and traffic incident management programs.

The FHWA provides tools, guidance, and best practices that aid local and state Departments of Transportation (DOTs) and their partners in their efforts to improve transportation efficiency and responder safety when a nonrecurring event interrupts transportation operations. Nonrecurring events include out of the ordinary traffic incidents, such as planning for a special event or disaster or emergency transportation operations, referred to as Disaster ETO. Partnerships in ETO program areas involve nontraditional transportation stakeholders, such as public safety management organizations including fire, rescue, and emergency medical services.

Emergency Shelters and Evacuations

Emergency Operations Centers (EOCs) are activated once a threat or risk of an emergency is established. EOCs can be established by the state or local government, although there is often miscommunication in terms of policy as to which department activates the EOC. There is not a clear connection between the Homeland Security Advisory System (HSAS) and the decision to activate an EOC. Most

are created at the city, county, or state level. Coordination across state boundaries for widespread emergencies is a challenge, although efforts are continuing to improve communication and coordination policies.

In major cities, emergency evacuation routes are designated in the event of an emergency or hazardous weather conditions. However, many regions still do not have such routes designated. Some cities and towns have identified traffic detour routes for road closures due to vehicle crashes, preplanned special events, and construction.

Very often, even the most extensive emergency evacuation plans are not coordinated across county lines or state boundaries, which makes routing systems incomplete and inconsistent. In some regions, the state highway operators and local agencies have not agreed upon plans to divert traffic from highways onto local streets. Another issue that emerges is the lack of traffic operations controls, including alternative traffic signal timing plans on local streets to accommodate such diversions.

Areas that do have developed emergency or evacuation plans often feel that these plans have not been adequately tested and exercised. Another factor is the weight and size of the vehicles utilizing the route. For instance, a large truck may not be able to pass a road with low overheads or its weight may surpass the allowed road limit on a particular route.

Emergency Resource Management

During emergencies, state and local resources operate at maximum capacity to respond to the emergency while maintaining other services as usual. Currently, no system is in place to determine how these resources should be allocated to the emergency while still maintaining resources for routine response capability. Although many state DOT personnel have experience in responding to emergencies, most indicate that they have had limited formal training in regional emergency response exercises and looking for suspicious activity. This lack of training impacts emergency preparedness and makes emergency planning difficult on such issues as prepositioning resources.

Because DOT personnel do not necessarily have identifiable uniforms or badges, they are difficult to spot initially during a crisis. This is especially problematic when there is a large-scale special event with assistance from many responders from multiple

agencies and regions; such events require security to be tightly controlled. In these cases, DOT-issued responder identification may not be recognized as adequate. DOT first responders need to participate in regional public safety or national first responder identification programs to ensure they are qualified to assist outside their local region. In addition to a lack of identifiable uniforms or badges, DOTs often lack enough professional personnel who can properly assess damage at the scene and the costs associated with it.

Although it is difficult to plan ahead for unimaginable events, natural disasters and terrorist attacks do occur and it is important to have a plan in place so local resources are not exhausted shortly after the incident when help is needed the most. Many regions are not fully prepared to handle mass casualties and may not have established procedures or locations to handle victims of the emergency. In the instance of a terrorist attack, some regions have expressed concern that shelter sites may become secondary terrorist targets because of the large concentration of people there.

Contracts between federal and local transportation operators and towing companies enable rapid clearance of individual incidents. This is especially critical when many vehicles may be damaged or abandoned, blocking emergency traffic.

Emergency Transportation Policy

When planning for an emergency, transportation planning agencies, such as state DOTs, may be able to funnel funding to certain emergency response activities and provide funding for evacuation planning, road improvements, and other elements that can be important in emergency response. Furthermore, the transportation planning agencies have traffic insight that can be vital in emergency route planning.

In terms of parking, several DOTs allow vehicle parking under transportation bridges and overpasses, including those in the interstate system. This is necessary in many urban areas that lack alternative parking facilities. Most regions lack a comprehensive policy addressing parking under transportation facilities, despite the potential dangers it poses.

Most transportation officials are aware of who has the authority to close roads in the event of an emergency within their state, although they are unclear as to whom to turn to when issues cross over into another jurisdiction. In almost all areas, the enforcement of a

quarantine was identified as problematic. Although clear authority to enact quarantines is assigned in all regions, very few cities and counties have plans or procedures for enforcing quarantines.

Communications between transportation agencies and law enforcement agencies on every level must be considered when assessing vulnerability of infrastructure or a region susceptible to terrorist attack. While many of these procedures have been evaluated, their findings have not been shared with other authorities called in during such events. Not only must they be shared but they also must be coordinated to allow for seamless integration in the event of an emergency.

Emergency Vehicles

An emergency vehicle is any vehicle operated by emergency personnel in response to a situation that may cause injury, loss of life, or damage to property. Generally, emergency vehicles include those driven by law enforcement agencies, those driven by fire and rescue services, those operated by emergency

Emergency vehicles typically display retroreflective and fluorescent markings that make them more visible to motorists. Between 1999 and 2009, more than one emergency worker per month was killed while aiding a motorist by the side of the road.

medical service providers (public and private), and the vehicles of towing and recovery service providers. Conventionally, such vehicles are equipped with lights and sirens and are visibly marked as affiliated with the authorizing agency.

Each state defines “emergency vehicle” within its legal codes, and these definitions vary considerably, ranging from any vehicle operated by public police, fire, or airport security agencies or designated as an emergency vehicle by a federal agency to a lengthy list that also includes park rangers, conservation agents, and civil defense authorities. Road rules governing emergency vehicles also vary by state. Because emergency vehicles in operation create an increased risk to those in the vehicle and to others on the roadways, safety of emergency personnel and of the general public is a national concern.

Costly Accidents

Between 1999 and 2009, more than one emergency worker per month was killed while aiding a motorist by the side of the road. More law enforcement officers

were killed in traffic-related incidents than from any other cause between 1998 and 2008. Seventy-one officers died in vehicle crashes or from being struck by a vehicle in 2008. From 2004 to 2006, 37,655 law enforcement injuries from crashes were reported.

Statistics for firefighters reveal the same pattern. From 1996 to 2007, vehicle collisions claimed the lives of 257 firefighters and another 53 firefighters died as a result of being struck by a vehicle. On average, about 25 percent of all firefighter fatalities are response or roadway scene related. One study estimates a fatality rate of 12.7 per 100,000 workers among emergency medical services (EMS) workers.

In addition to the loss of life, emergency vehicle accidents result in delayed emergency service, which can result in further loss of life. For example, a one-minute delay can drop the chance of survival for a cardiac arrest patient from 80 percent to 30 to 40 percent. Vehicle replacement runs from a low of \$40,000 for a high-performance police car to more than \$750,000 for a fire truck. Even more costly, lawsuits can strain the resources of already overburdened local governments.

Improving Safety

Emergency vehicles typically include warning lights, sirens and horns, and retroreflective striping, which reflects light back to its source. These features are designed to make other drivers aware of the size, speed, and location of emergency vehicles. Yet both the number of accidents and the average response time show that traditional measures are not fully effective. Research suggests that speeding to the scene of an emergency endangers drivers and occupants of emergency vehicles as well as other vehicles on the road and does little to improve aid or response time. One study concluded that lights and sirens saved about a minute off the average response time.

The U.S. Fire Administration and the Society of Automotive Engineers conducted a two-part study funded by the National Institute of Justice in 2003 and 2005 that examined the use of warning lights. Based on their findings, the researchers recommended three changes in the way emergency vehicles use warning lights. Because warning lights that are visible at night may be significantly less visible in daylight, they recommended increasing the current intensity of warning lights sufficiently to attract the attention of daytime drivers, or even better, that two levels of light intensity be used. Blue lights proved

more effective than red or amber at drawing attention to vehicles in both day and night tests. They also recommended using different colored lights to make a clear visual distinction between vehicles parked in the normal path of traffic and vehicles that may be near the normal path of traffic but are not obstructing it.

The Standard for Automotive Fire Apparatus of the National Fire Protection Association (NFPA) requires fire trucks and ambulances in the United States to have retroreflective striping and markings in multiple locations. Compliance with the NFPA standard is not mandatory, but vehicle manufacturers generally comply. Although law enforcement lacks a similar national standard, many law enforcement agencies use retroreflective markings on vehicles. Because stealth may sometimes be a priority for law enforcement, high visibility is not always appropriate.

A separate study looked specifically at retroreflective striping, high-visibility paint, built-in lighting, and other reflectors on emergency vehicles. The researchers found that retroreflective materials can aid in increasing visibility of emergency vehicles (especially at night), contrasting colors can help civilian drivers see a hazard, and fluorescent colors (especially fluorescent yellow-green and orange) yield higher visibility for daytime motorists. The researchers recommended improvements that included using retroreflective material to outline an emergency vehicle with “contour” or “edge” markings, especially on large vehicles; placing retroreflective material lower on emergency vehicles to take advantage of headlights from approaching vehicles, using fluorescent retroreflective material for maximum visibility during day and nighttime hours, and applying distinctive logos or emblems made with retroreflective material to improve both visibility and recognition of emergency vehicles.

The “Move Over” Law

Section 2014 of the 2005 Safe, Accountable, Flexible, and Efficient Transportation Equity Act: A Legacy for Users (SAFETEA-LU), titled First Responder Roadside Vehicle Safety, required the National Highway Traffic Safety Administration (NHTSA) to develop a program to address the safety of first responders. One of the things NHTSA did was to work closely with the National Conference of State Legislatures (NCSL) and the National Committee on Uniform

Traffic Laws and Ordinances (NCUTLO) to develop a model “move over” law. In 2012, Hawai‘i became the 50th state to pass a move over law, requiring motorists who are approaching an emergency vehicle on the side of the road with its emergency lights flashing to move over into the opposite lane or to slow down—in some cases to 20 miles per hour below the posted speed limit—if moving over is not possible. Each state has its own penalties for those who fail to comply. These include fines from \$40 to \$500, points on the offender’s driving record, license suspension, or even jail time. Polls indicate that 90 percent of Americans believe traffic stops and roadside emergencies are dangerous for law enforcement and first responders.

Emerging Technologies

Within the field of transportation, the term *emerging technologies* typically refers to those technologies that are being developed in order to help people move faster, at greater volumes, or with greater

A manager at NASA's Marshall Space Flight Center's Interstellar Propulsion Research Center holds a sample of a light, rigid carbon fiber material for use in a solar sail, which could harness pressure from radiation to propel spacecraft. The material's density is less than one-tenth of an ounce per square yard.

efficiency. In all fields, emerging technologies represent progressive developments that emerge within a field, typically for competitive advantage. Because of their newness, some of these technologies may seem ridiculous. This is the stuff of the future, but what previous generations may have called ridiculous is now part of everyday life. Within the field of transportation, these advances and innovations can range from bicycle technology to interstellar travel. Some of the most promising currently emerging technologies include those in the fields of automobiles, trains, aviation, and space travel.

Automobiles

Innovations in automobiles are typically concerned with fuel efficiency but may include other areas where the standard automobile is less than optimal. One such innovation that has been of great interest is the airless tire. Such nonpneumatic tires (NPT) would not be supported by air pressure. This type of

tire has already been developed for some vehicles, such as riding lawn mowers, golf carts, and backhoes. Unfortunately, nonpneumatic tires typically provide less suspension and less heat dissipation; either of these features currently make nonpneumatic tires unusable for automobiles. The primary areas of research toward solving these problems focus on the development of new polymers that may be able to better absorb shocks and dissipate heat created by the friction of use.

Driverless cars have also been of interest to automotive innovators. Google has been the most recent corporation to take interest. Google recently won awards from the Department of Defense for its development of a particularly promising driverless car. Until recently, these innovations were somewhat irrelevant as U.S. laws forbade the use of driverless cars on American roads. However, laws passed since 2011 in multiple states allow for the use of driverless cars.

By far, the area of greatest interest within emerging automotive technologies is that of alternative fuel vehicles. These technologies are needed to prepare for the inevitability of peak oil, the point at which the rate of petroleum extraction reaches the maximum and after which the rate of production is expected to reach terminal decline. While the situation is dire, these technologies have been difficult to adopt due to industry resistance and the substantial infrastructure adjustments needed to adopt them. Denatured ethanol mixes have already been used in the United States to some success. The two most common blends are E15 and E85. E15 is made up of 15 percent ethanol and 85 percent gasoline. The major advantage of this blend is that it can be used in any automobile made after 2001, and it is already widely available. E85 is made up of 85 percent ethanol and 15 percent gasoline. E85 can only be used in specially designed flex-fuel vehicles, but it is also widely available in the United States. Diesel has long been preferred over gasoline for its greater fuel efficiency; biodiesel, which is typically made from vegetable fat, has the added advantage of being derived from renewable resources. Electric automobiles are also of interest, as they allow for the use of energy as clean as is available on private or public energy grids. Other nonpetroleum fuels that have been explored include hydrogen fuel cells, steam, charcoal, ammonia, and dimethyl ether.

Aviation and Trains

Aviation innovation tends to focus on going very far distances quickly. Supersonic flight has been of interest to aviators since the mid-20th century. However, supersonic flight causes sonic booms that can be disruptive to neighboring communities and wildlife. Within the realm of supersonic flight, the scramjet, which is a supersonic combustion ramjet, allows for sustained propelled hypersonic flight that could travel any place on Earth in 90 minutes. While this technology has existed since the 1950s, it has only recently become more viable for military or civilian use.

Emerging technologies in locomotives are primarily focused on technologies that will mechanically simplify the track and increase speed. Hovertrains achieve these goals by replacing conventional steel wheels with hovercraft lift pads. This eliminates rolling resistance, thus allowing for very high speed while simplifying infrastructure. Similarly, maglev trains use magnetic levitation to raise trains above the track and propel them with incredibly strong magnets instead of wheels. Like hovertrains, these mechanically simplify the cars while increasing speed.

Space Travel

Among the most exciting experimental space technologies are space elevators, solar sails, and ion thrust engines. Space elevators have been proposed as a means to take personnel and materials into space without the need for massive engines or breaking the Earth's gravitational pull. A space elevator would consist of an orbital station attached to the Earth with a cable composed of very strong advanced materials, likely engineered on the molecular scale. Solar sails and ion thrust engines are proposed methods that could potentially make it possible to travel between stars. Solar sails are made of ultrathin mirrors; these sails would be propelled using radiation pressure to reach very fast speeds gradually. Ion thrust engines are a type of technology that is currently being developed to accelerate spacecraft via electric propulsion.

Emissions Modeling

Transportation is a major contributor of greenhouse gas and pollutant emissions. Among the various transportation modes, on-road motor vehicles are the most significant sources of transportation-related emissions. The ability to model emissions from these sources is essential in making informed decisions on transportation programs and investments as well as in forming sustainable transportation and climate change policies.

Modeling vehicle emissions can range from a simple exercise to a complicated task. The choice of the modeling approach depends on the purpose of the analysis, the available data and tools, and

the level of accuracy expected. Different modeling approaches have their own strengths and limitations and are suitable for answering different types of policy questions.

Needs for Emissions Modeling

There are several needs for the modeling of transportation-related emissions in planning and policy analysis. In a broad sense, emissions modeling is conducted to develop emissions inventories. Historical and current emissions inventories are used by policy makers to assess emissions trends, understand the contribution of each emission source, develop strategies to reduce emissions, and track progress over time. Future emissions inventory forecasts are used to assist in the selection of appropriate emissions reduction strategies and to establish emissions reduction goals.

In the context of planning, emissions modeling is performed by transportation agencies to evaluate the potential impacts of transportation plans, programs, and projects on air quality in their areas. In the United States, this is required of agencies in nonattainment areas, which do not meet one or more of the National Ambient Air Quality Standards (NAAQS). The requirement, referred to as transportation conformity, aims to ensure that federal funding and approval are given to highway and transit projects that will not lead to new air quality violations, worsen existing violations, or delay the ability of an area to attain the standards.

Some transportation policies are partly driven by the desire to reduce emissions from on-road motor vehicles. For example, U.S. federal policies encourage construction of high occupancy vehicle lanes instead of general-purpose lanes in nonattainment areas. Many policies that are aimed at reducing traffic congestion also have a cobenefit of reducing traffic emissions. Examples include congestion pricing, car sharing, transit improvement, etc. Emissions modeling can be performed to analyze the emissions reduction benefits of these policies.

In addition, emissions modeling can play a role in the analysis of policies related to other issues as well as transportation. For example, emissions modeling is one of the key modeling steps required to determine the level of transportation-related air pollution near roadways. The modeling results can have implications for public health and land use policies. For example, sites with a high fraction of

sensitive populations, such as schools and nursing homes, should be located far enough away from major highways.

Macroscopic Approach

Emissions from transportation sources can be modeled in many ways. For modeling at the macroscopic level, data input requirements are minimal and the modeling approach is not sophisticated. On the other hand, modeling results are sensitive to only a limited set of variables, which limits the range of policy questions that can be addressed. For example, at the national or state level a spreadsheet tool can be used to model carbon dioxide emissions based on fuel sale records. However, this method will not reveal, for instance, whether the reduction in carbon dioxide emissions is a result of reduction in vehicle miles traveled or improvement in vehicle fuel efficiency.

At the regional level, areawide analysis tools can be used to estimate average emission results for a region. For example, TCM Tools is a sketch-planning tool designed to estimate the change in vehicle activity and emissions resulting from a wide range of transportation control measures such as implementing flexible work hours and improving transit services in the region. The tool provides emission estimates at the regional or areawide level. It cannot estimate emission impacts for specific roadways or locations in the region.

Mesoscopic Approach

Unlike the macroscopic approach, the mesoscopic emissions modeling approach can relate changes in vehicle fleet mix and travel behaviors to the resulting emission changes. It involves determining the amount of vehicle activity (for example, miles traveled or hours operated) and the corresponding vehicle emissions rates (for example, grams per mile or grams per hour). As vehicle emission rates vary by a number of factors, including vehicle characteristics (vehicle type, engine technology, etc.), roadway characteristics (road type, road slope, etc.), and traffic conditions (speed, congestion level, etc.), vehicle activity would need to be characterized by these factors as well.

As an example, carbon dioxide emission rates (per unit distance) of cars and trucks vary greatly by travel speeds. They are lowest at the moderate speeds of 35 to 50 miles per hour and higher at

lower and higher speeds. Modelers need to determine the number of miles that vehicles travel at different speeds. Then, the number of miles at each speed is multiplied by the emission rate for the corresponding speed, and the results summed across all the speeds indicate the total emissions.

The mesoscopic approach has traditionally been used by transportation agencies and metropolitan planning organizations to analyze the emission impacts of transportation plans, programs, and projects such as widening roads and adding new transit routes. Travel demand models are often used to generate vehicle activity data inputs in terms of vehicle miles traveled or vehicle hours traveled. Vehicle emission rates are usually obtained from the U.S. Environmental Protection Agency's MOVES model, or in the case of California, the California Air Resources Board's EMFAC model. Then, the emission impacts for specific roadways or locations as well as for the entire region can be analyzed.

Microscopic Approach

For analyses of the emission impacts of some transportation projects and technologies, a highly detailed modeling approach that can capture the effects of driving behavior on vehicle emissions is needed. This microscopic approach calculates emissions at high time resolution, typically on a second-by-second basis, as it accounts for the modal operations of vehicles, such as acceleration, deceleration, and idling. For example, carbon dioxide emission rates (per unit time) of cars and trucks are much higher during acceleration than during cruising.

Therefore, traffic flow improvement projects and intelligent transportation system technologies that reduce the number of stops and smooth the traffic flow, such as traffic signal synchronization and ramp metering, can result in reductions of carbon dioxide emissions. Although the microscopic emissions modeling approach provides more accurate emission results than the mesoscopic approach, it is more computationally demanding and requires more extensive data inputs. Thus, it is used more frequently in project-level analyses (such as modeling carbon monoxide and particulate hotspots) than in areawide analyses (for example, regional emissions inventory development).

This modeling approach requires traffic microsimulation tools to produce modal vehicle activity

data inputs in the form of vehicle trajectories (that is, second-by-second position and speed profiles). These vehicle trajectories are used in conjunction with microscopic vehicle emissions models such as MOVES and CMEM to calculate the corresponding emissions. These emission results can then be aggregated for specific roadways or locations as well as for specific time periods in the modeling domain.

Emissions Trading Schemes

The existence of a relationship between emissions trading schemes and the airline industry is a relatively recent phenomenon. The 2012 incorporation of the aviation sector into the European Union's Emissions Trading Scheme (EU ETS) represented the first time that an application of this market-based instrument has been used in an effort to mitigate airline carbon dioxide (CO₂) emissions. As

such, the knowledge and experience of the relationship between emissions trading schemes and their effects on airlines is limited to what one knows of the European experience in this regard.

Emissions Trading in the European Union

The European Union launched the EU ETS, the world's largest and first transfrontier cap-and-trade scheme, in 2005 as part of its policy response to ensure compliance with its Kyoto Protocol target. In cap-and-trade, annual allowance allocations (tons of CO₂ per annum) are made to participants with the rule that participants hold sufficient allowances at the end of the year to cover their emissions or face the imposition of a financial penalty. (Emissions trading schemes can also take the form of baseline-and-credit, which is not a focus of this article.) Participants are able to sell and buy allowances as they wish, and it is this "trade" element of cap-and-trade that produces an allowance price. This price signal provides an incentive to those for whom abatement is relatively cheap and to sell their surpluses to those for whom abatement is relatively expensive.

Those facing difficulty in keeping their emissions in line with their allocations have a choice between taking measures to reduce their emissions (for example, investing in more efficient technology, using less carbon-intensive energy sources, etc.) or buying allowances on the market, or a combination of the two. Such choices are likely to be determined by relative costs of the different abatement options. In this way, emissions are reduced wherever it is most cost-effective to do so. The existence of an allowance price also provides an economic incentive for technological innovation, as surplus allowances arising from any technological development can be sold. The economic literature typically refers to this innovation aspect of emissions trading as "dynamic efficiency."

Since 2005 a cap has been fixed on CO₂ emissions for the EU's power and heavy-industry sector (refineries, cement, iron and steel, glass, ceramics, paper, and board) during two trading phases (2005–07 and 2008–12). EU ETS coverage accounts for approximately half of the EU's CO₂ emissions and 45 percent of total greenhouse gas emissions. In 2008, the EU in its Climate and Energy Package outlined plans to extend the EU ETS to a third phase from 2013 to 2020. In the same year the EU

adopted legislation that would result in emissions from international aviation (including both EU and non-EU airlines) being included in the EU ETS from 2012.

Aviation in the European Union's Emissions Trading Scheme

The EU decision to include aviation in the EU ETS was driven by two main factors: sectoral emissions growth and international policy inertia. Since the late 1980s the aviation sector has experienced substantial growth, with J. Vespermann and A. Wald (2011) highlighting an annual average sectoral growth rate of approximately 5 percent between 1989 and 2009. The International Civil Aviation Organization (ICAO) anticipates that the 2012–30 period will see carried passenger numbers grow at an annual average of 4.5 percent, reaching 6.3 billion by 2030. Airbus projects a doubling of aircraft fleets over the 2006–26 period. While continual aviation sector growth is welcomed from an economic perspective, such growth poses considerable environmental challenges. By 2020 global international aviation emissions are projected to be approximately 70 percent higher than 2005 even if fuel efficiency improves by 2 percent per year, and it could further grow by up to 700 percent by 2050. Within the EU, direct emissions from aviation account for approximately 3 percent of the EU's total greenhouse gases, with the large majority of these emissions coming from international flights.

The 1997 Kyoto Protocol dictated that international aviation emissions be excluded from the greenhouse gas emissions targets assigned to developed countries and instead entrusted ICAO with the responsibility for developing policies and measures to address the challenge of "limiting" or "reducing" the emissions of this sector. Since the Kyoto Protocol the EU has sought a global agreement developed through ICAO to tackle aviation emissions. However, failure within ICAO thus far to deliver such an agreement or substantive policy and measures compelled the EU to act to address this challenge, culminating in the 2008 decision to include emissions from international aviation in the EU ETS from 2012.

The European Commission's incorporation of the aviation sector into the EU ETS resulted in a CO₂ emissions cap being imposed on all international flights—from or to anywhere in the

world—that arrive or depart from an EU airport from 2012 onward (including flights arriving at or departing from airports in Norway, Iceland, and Lichtenstein; very light aircraft; military, police, customs and rescue flights, flights on state and government business, and training or testing flights are excluded). The EU ETS thus applies to any aircraft operator, whether EU or foreign based, operating international flights on routes to, from, or between EU airports. Such an approach ensures all airlines are treated equally. The European Commission estimates that by 2020 some 183 million tons of CO₂ will be saved per year on the flights covered by the EU ETS. This emissions saving represents a 46 percent reduction compared to “business as usual.”

Emissions Trading Scheme Effects on Airlines

The principal means by which participation in an emissions trading scheme will impact airlines is the financial implications of such participation, with the scale of financial impacts determined by the allowance allocation that airlines receive. In determining the allowance budget for the aviation sector, the European Commission used the 2004 to 2006 period as the baseline for aviation emissions. The commission used this period instead of 1990 because it takes account of the significant growth of the aviation sector since 1990. As the objective of an ETS is to bring about emissions reductions, allowance budgets are typically less than 100 percent of historical emissions, thereby ensuring participants will face an allowance shortage. For 2012 the allowance budget was equivalent to 97 percent of average historical emissions over the 2004 to 2006 period. From 2013 onward, the allowance budget will be reduced to 95 percent of historic emissions.

The allocation of the allowance budget would be facilitated through a combination of benchmarking and auctioning. Eighty-two percent of allowances are allocated to airlines for free via an emissions efficiency performance benchmark. The free allocation of allowances via benchmarking as opposed to grandfathering (allocation based on historical emissions) is seen to reward airlines that undertake early action to reduce their emissions and/or modernize their fleet through investment in more efficient planes with lower emissions output. (Within the EU ETS benchmarks were calculated on the basis of the

number of passengers and freight volume carried and total distance traveled for each airline operator in 2010.) Fifteen percent of the allowance budget is auctioned, and the remaining 3 percent is allocated to a special reserve for later distribution to fast-growing airlines and new entrants into the market.

When details of the commission’s allocation methodology first emerged, the aviation industry expressed concerns that despite receiving 82 percent of their allowances for free, the sector could be faced with significant economic costs (allowance purchase, airline efficiency improvements, fleet upgrades) as a result of inclusion in the ETS. In 2011 the China Air Transportation Association forecast that it would cost the Chinese airline sector 800 million Yuan (\$123 million) in EU ETS compliance costs in 2012 and more than triple that by 2020. For the United Arab Emirates, estimated compliance costs will range between 500 million and 1 billion euros, with Etihad expecting to spend upward of \$394 million between 2012 and 2020.

However, similar to the way the airline industry passes on increases in oil prices and airport charges to passengers in the form of increased ticket prices, passengers can also expect airlines to pass on the cost of their participation in an emissions trading scheme. European Commission (2006) modeling of this issue identified that, assuming airlines fully pass on their EU ETS compliance costs, by 2020 passengers could expect to see an increase in short-haul return ticket prices of between 0.9 and 4.6 euros, with long-haul tickets increasing by 4 to 19.8 euros. European Commission analysis concluded that such price increases would have a negligible effect on projected passenger demand growth up to 2020 due to the demand for airline travel being relatively price inelastic. PointCarbon reported that within the first fortnight of 2012 four U.S. carriers—American Airlines, Delta, United Continental, and US Airways—imposed a \$3 passenger surcharge on their European-bound flights.

Airline Experience With ETS

The EU decision to include both EU and non-EU airlines in the EU ETS was not met with resounding international support. Many non-EU countries (principally the United States, China, India, and Canada) questioned the legality of the EU’s aviation ETS plans, noting that it violates the sovereignty of their states, and threatened significant retaliatory

action. The U.S. airline industry, represented by the American Transport Association (ATA), launched a legal challenge against the EU over its inclusion in the EU ETS. On December 21, 2011, the European Court of Justice confirmed that the EU's aviation ETS legislation does not infringe international law, the principles of territoriality, or the sovereignty of third countries since the scheme is applicable to airline operators only when their aircraft are physically in the territory of one of the member states of the EU. In spite of the court ruling, China in early 2012 banned its airlines from participating in the EU ETS without government approval. In November 2012 President Barack Obama signed into law the European Union Emissions Trading Scheme Prohibition Act of 2011, which prohibits U.S. airline operators from participating in the EU ETS. China also indicated a willingness to consider the imposition of some form of trade restrictions on the EU, such as the delay or cancellation of purchasing new aircraft by its airlines from European manufacturer Airbus.

November 2012 saw non-EU airlines receive a temporary reprieve regarding the EU ETS when the European Commission announced its "stop the clock" policy, which suspended for a year the participation of non-EU airlines in the EU ETS. The Commission's initiative was driven by progress during the November 2012 ICAO Council meeting at which ICAO highlighted the potential for developing a global market-based measure to deal with aviation CO₂. ICAO is currently considering the potential of developing a mandatory offset or a global ETS. Though ICAO discussions are at an early stage, a global ETS would work in a similar fashion to the EU ETS, while an offsetting approach would require airline operators or their parent countries to purchase credits to cover airline CO₂ emissions above a predetermined baseline. In order to give ongoing international aviation talks a better chance of successfully agreeing on a global market measure, the commission agreed to stop the clock on the implementation of the international aspects of its EU ETS aviation until after the ICAO Assembly in September/October 2013. The implication for airlines of this EU policy is that non-EU airlines were not required to surrender allowances to the EU in April 2013 to cover their emissions for 2012. However, airlines operating flights within and between member states would continue to be part of the EU ETS with the associated compliance obligations.

While the EU is optimistic that a global solution can be reached at the upcoming ICAO Assembly, it has reminded all non-EU airlines that failure to reach a satisfactory agreement will see the EU reinstate all EU ETS obligations. The EU ETS aviation legislation is designed such that it can be amended to reflect the implications of a global agreement. Regarding the development of an ICAO market based measures, the EU has highlighted that such a measure must include three key elements:

1. It must deliver aviation emission reductions at least as large as the EU ETS is doing.
2. It must be nondiscriminatory for all airlines.
3. It must contain targets and measures for ICAO member countries.

Conclusion

While airline experience operating within an emissions trading scheme is relatively limited to date, the outcomes from the 2013 ICAO Assembly will go a long way to shaping whether the aviation sector will have to develop a more long-term relationship with emissions trading—within the EU or as part of global scheme—or some other form of market-based measure. As the aviation community looks toward the 2013 Assembly, the focus for those airlines not exempt from EU ETS participation was on the EU's evaluation of 2012 compliance. Data released by the European Commission in 2013 revealed that airlines responsible for 98 percent of the 2012 aviation emissions regulated under the EU ETS had surrendered sufficient allowances to demonstrate compliance. A European Commission official speaking to PointCarbon identified that Chinese and Indian airlines operating commercial flights within Europe were noncompliant with their ETS obligations. With Chinese and Indian airlines continuing to oppose aviation in the EU ETS, in spite of the "stop the clock" policy for non-EU flights, this issue raises the prospect of the EU facing a significant international political battle should ICAO fail to deliver substantive progress on a global aviation agreement and force the EU to once again "start the clock."

Employment Location

Urban historians and sociologists have well documented the exodus of affluent, middle-class, and working-class Americans from the inner cities to the suburbs beginning in the 1950s and continuing well into the 1970s. Following the trend, employers and industrial centers gradually transferred jobs to the suburbs, creating an employer, employee, and transportation triangle with paradoxical, policy, and political problems needing to be solved for 21st-century transportation growth and climate health.

People and Jobs Exit the Cities

Statistics from the U.S. Department of Labor reflected employment patterns from 1950 to 1980 following the footsteps of exiting people. In their 1986 article "Suburbs and Satellites: Two Decades of Change" appearing in the *American Sociological Review*, sociologists J. R. Logan and R. M. Golden reported that manufacturing jobs grew 16 percent in the suburbs between 1958 and 1963, but decreased 6 percent in central cities. Between 1963 and 1977, manufacturing jobs dropped by 700,000 in metropolitan areas but grew by 1.1 million jobs in the suburbs.

The same trend proved to be true for retail and wholesale employment, which declined by 100,000 during the same years while the suburbs gained 1.8 million jobs. While this combination of migration-stimulated job decentralization and employment located in the suburbs encouraged people to live in the suburbs, the trend slowed after the 1970s and 1980s.

As the suburbs grew, so did the use of automobiles and so did commuting problems. Long, tiring commutes on congested freeways reduced job productivity, yet centralized employment districts located in cities benefited employers sharing ideas, workers, and clients. Proximity to other businesses, especially related industries, was an important competitive factor for businesses, and the best climate for these conditions occurred when jobs and businesses were concentrated into centers.

Decentralization and Inner City Poverty

Harvard economist John Kain first advanced the spatial mismatch thesis in a 1968 article in the *Quarterly Journal of Economics*. He studied the locations of homes of African Americans in Detroit and

Chicago and trends in the locations of employment opportunities in both cities, and he discovered that while businesses were decentralizing at a rapid pace, housing discrimination, poverty, and inadequate public transportation connections prevented African Americans from following jobs to the suburbs. Subsequent studies including a 1998 study by Keith Ihlanfeldt and David Sjoquist of Georgia State University reinforced Kain's findings and suggested that the 1960s patterns became more entrenched as low-income and minority populations remained concentrated in central city locations while businesses continued to decentralize rapidly. In the 1990s, welfare reform initiatives catapulted access to jobs into a central public policy question in states and metropolitan regions across the United States and caused public officials to reexamine transportation links between welfare recipients and job locations.

In 2000, complying with President Bill Clinton's 1994 executive order on environmental justice, the Federal Highway Administration required metropolitan planning organizations (MPOs) to demonstrate that regional transportation plans addressed the transportation needs of low-income and minority populations. More recently, geographic information systems (GIS) technology improved the analytical capabilities of spatial mismatch research by giving researchers the tools to pinpoint percentages of low-income households within walking distance of public transit in a region and the percentage of job opportunities located within walking distance of public transportation.

From Suburbs to City

During the 2000s, the city-suburbs job decentralization issue in America reached an unexpected tipping point. A 2013 Brookings Institution book by Elizabeth Kneebone and Alan Berube, *Confronting Suburban Poverty in America*, reported that between 2000 and 2011, the number of suburban poor people in the United States grew by 64 percent, doubling the rate in the cities and proving that more poor people live in the suburbs than in the inner cities.

The book suggested that many suburbs do not have public transit networks connecting impoverished neighborhoods to job opportunities and people tend to be scattered over larger areas in the suburbs. Suburbs usually do not have the built-in service provider networks that inner-city communities have established over the decades. The authors emphasized

that the overall picture is a mixed one when they said that some poor people living in the suburbs enjoy the benefits of better housing, safer neighborhoods, and higher achieving schools than in cities. They noted that others face "lengthy, costly commutes to work, a lack of reliable transportation, and an absence of basic health and social services that are often more fully available and established in cities."

The Northern California Megaregion Pattern

Northern California contains nearly 60 Fortune 1000 companies, with only one-third of them based in the megaregion's central cities of San Francisco, San Jose, Sacramento, and Oakland. California State Senate Bill 375 calls for transportation planning that reduces driving and specifically discusses housing planning measures that are equally important for employment. Sprawling patterns of job location heighten the need for vehicles and highways and discourage regional public transit.

This pattern repeats itself in megaregions across the country, a pattern of sprawling job growth that challenges 21st-century development. As the boundaries of megaregions expand outward, they produce unsustainable commute patterns, car-oriented suburbs, and increased greenhouse gas emission levels. Regional planning and employment patterns need to change if the United States and the rest of the world are to meet the challenges of climate change.

Slowing the continued outward growth of jobs from developed employment centers and shifting commuters into sustainable commute modes will take coordinated planning at political, corporate, and individual levels. A few beneficial planning measures include shifting more work back into traditional transit-served downtowns, concentrating more employment at suburban transit stations, remaking existing low-density office parks into higher density employment districts that could be served by transit, reforming self-enclosed car-oriented companies, and increasing telecommuting and distance learning.

A vision recognizing the multicenteredness of a megaregion but reshaping the geography for a 21st century with increasing nondriving alternatives is an essential part of a plan to combat climate change and ensure economic growth.

transportation. Energy costs therefore affect consumer choices during the selection of mode of transport and even whether to travel at all.

Transportation is a key activity to economic growth. The cost of transportation has overall declined—largely as a result of technological improvement. Vehicles have become more efficient. Furthermore, improvements in manufacturing have resulted in improvements in durability and longevity, resulting in a decreased need for maintenance and improvement. However, with finite resources available, the cost of energy to power transport is set to rise in the long term. Furthermore, many believe that the “external costs” of using dirty sources of energy should be factored into the price consumers pay for energy through eco-taxes or carbon pricing. This has the potential to change the economics of transportation in the future.

Oil Supply and Demand

At present, the U.S. transportation system is primarily reliant on oil as the principal source of energy for automotive, marine, and aviation applications. With any extractive resource, there is a balance between supply and demand and the cost that can be charged for a unit of fuel used to deliver primary energy.

Fossil fuels are in finite supply. The oil geologist Marion King Hubbert made a prediction that has come to be known as “Hubbert’s peak” or “peak oil.” This prediction follows that extraction and consumption of any natural resource will follow a “bell-shaped curve.” Here, the y axis represents oil extraction, while the x axis represents time passing. At the top of the curve, the condition of “peak oil” is said to have been reached. This is the point at which extraction reaches its highest rate. After that point, it becomes increasingly hard to locate and realize new oil reserves. Once peak oil has been crossed, extraction of that finite resource can only enter a period of decline and scarcity. Understanding this graph is crucial to realizing that the price of fossil fuels can only ever escalate in the period of time leading up to peak oil and will rise sharply in the immediate aftermath.

There is some uncertainty globally about the point at which peak oil will be reached, as it is hard to know how much oil is ultimately recoverable globally. It is, however, known that the United States reached its peak of oil production during

Energy Costs

All modes of transportation require energy in one form or another to move goods and services from one place to another. Energy costs form one of the most significant components of the overall cost of

the 1970s. As oil that is easy to extract becomes in ever constrained supply, attention has turned to nonconventional oil sources—such as those that can be obtained from tar sands. These reserves come with vastly increased external costs to the environment. Nonconventional oil resources are highly carbon intensive to utilize. Being of poorer quality, they require additional energy to extract and refine into usable petroleum products. There is also concern that the extraction of nonconventional oil resources causes massive environmental degradation.

Oil supply—and hence price—is controlled by producers internationally. In this respect, one of the largest supplier blocs is OPEC, the Organization of Petroleum Exporting Countries. This is a cartel of oil-producing countries that work together to maintain the price of oil in the short term, while also ensuring a steady supply to consumers.

There is a global geopolitical dimension that can affect energy prices. Instability in countries that produce oil can lead to oil prices escalating, as the market attempts to compensate for perceived potential challenges with supply.

One of the determinants of oil demand globally is the level of economic activity. When global economies and markets are strong, there is high demand for fossil fuels to power the economy. As economic activity declines, so there is less demand for fossil fuels.

1973 Oil Crisis

In the early 1970s, the United States had passed its peak of oil production. James Akins was asked by President Richard Nixon to audit the U.S. oil production capacity and found, alarmingly, that there was no spare capacity. That year, there were tensions in the Middle East and a conflict began to escalate between Egypt and Syria, with other Arab nations, and Israel. Because of the U.S. support for Israel, the OPEC countries decided to raise the price of their crude oil output dramatically. This had manifold implications for Western economies. This sudden change in energy prices shaped Western attitudes to oil exploration and discovery and energy-efficiency measures. For a brief period there was resurgent interest in alternative technologies to oil for transport applications and a brief period in which manufacturers brought smaller and more economical vehicles to the marketplace.

While prices eventually stabilized, the effects of the oil shock were lasting in that it alerted governments to the impact of rising energy prices on transportation activities and the economy.

Energy Costs in Transportation

The costs of energy have to be situated in a wider landscape of transportation costs. They are just one factor that affects the economies of transportation. That said, it is a given that primary energy costs will rise in the long term.

Running private cars is much less economical than public transport vehicles. As private cars often spend a significant proportion of their life span unused and idle, they have poor capacity utilization. As a result, for private vehicles, factors such as depreciation have a bigger impact on the cost per passenger mile traveled. Energy costs are just one of the plethora of costs vehicle owners face—there is also the cost of repair and maintenance, insuring the vehicle, taxes and registration fees, and costs for using the vehicle, such as tolls and parking charges.

For commercial vehicles with high rates of utilization, energy factors figure more heavily. In the road haulage industry and shipping and aviation, energy costs are a more significant element of the cost per vehicle mile traveled. Furthermore, at present, some areas, such as shipping and aviation, are largely exempt from taxes on the fuels they consume as a result of international agreements. There is pressure to recognize the “external” environmental costs of using dirty energy sources. Additional taxes levied on fuel could in the future add to the energy costs of these transportation industries.

While the cost of energy has risen, to some degree this has been offset by improvements in engine design leading to more efficient engines and improvements in manufacturing resulting in cheaper, more durable vehicles; this has meant that while the cost of energy has risen, the cost of transportation has in real terms fallen.

There are, however, technological limits to how much improvements in existing gasoline engine efficiency will be able to improve to balance out the escalating costs of primary energy. As energy prices escalate and efficiency improvements diminish, there will be a point at which energy costs become more dominant in the transport economics equation.

Fuel Tax

Fuel tax, also known as fuel duties and fuel excise, is a tax applied by the government to oil products. Often, the rate of tax applied to fuels used for road transport differs from the rate levied on fuels used for agricultural purposes or for home heating. Fuel tax systems can be designed as ecological taxes, to promote the use of alternatives to fossil fuel. Here, biofuels, which provide the same function—albeit from a natural source—may be taxed at a lower rate than fossil fuels to incentivize their use. Fuel taxes are implemented at different rates around the world according to country. European countries tend to impose high fuel taxes, while the United States, Canada, and Australia tend to have low fuel taxes.

In some countries where fuel used for agricultural or home heating purposes attracts a different rate of tax, the fuel can be “dyed” using a colorful hydrocarbon dye. This helps prevent tax avoidance by staining not only the fuel, but the tank of the vehicle the fuel is used in. Should dyed fuel attracting a lower tax rate be used in a road vehicle, the infringement can easily be detected by “dipping” the tank. In order to try to circumvent this duty, criminal organizations have been known to carry out a process called “fuel laundering” in which cheap, agricultural fuel is stripped of its color through a chemical process, producing “clear” or white diesel, identical to road diesel. In addition to evading excise, there are also consumer concerns that this illegal fuel can be of an inferior quality and damage vehicles.

While fuel for motor vehicles is generally taxed, fuel for marine purposes has largely been exempt from taxation. Internationally, there are a large number of bilateral service agreements in place between various countries.

Aviation is another area that benefits from lower taxes on fuels. For international commercial aviation, there are often bilateral service agreements in place between countries, resulting in tax exemption for fuel used for international commercial flights. Often there are different tax regimes in place for domestic flights. Furthermore, fuel for general aviation may be taxed differently than commercial aviation.

As of 2013, existing international climate agreements have focused on the regulation of emissions from land-based activities. There is international consensus in the scientific community that drastic reductions in carbon emissions will be needed to halt the prospect of irreversible anthropogenic

A sign in the window of a U.S. gas station limits fuel purchases during the height of the oil crisis in 1973. The crisis began when OPEC countries raised the price of their crude oil output, leading to a spike in gasoline prices of nearly 400 percent between October 1, 1973, and January 1, 1974.

(man-made) climate change. Politically, it has been more challenging to achieve a consensus on what action is required to reduce carbon emissions globally.

Bunker fuel, heavy fuel used for shipping, accounts for around 5 percent of global carbon emissions. It also is used to facilitate around 80 percent of global trade. Therefore, the market is sensitive to the cost of bunker fuel. There is a direct relationship between fuel taxes and vehicle usage. Where fuel taxes are raised, they modify consumer behavior. In the short term, these are changes in consumption behavior—with drivers choosing to drive less. Where fuel taxes are held high in the longer term, they can affect vehicle purchasing decisions. High fuel taxes over time may result in drivers choosing smaller, more fuel-efficient vehicles.

Many have said that carbon taxes on shipping and aviation look to be a likely climate mitigation measure for the future. This could lead to reductions in use of air transport and shipping services. This is likely to have far-reaching social consequences and may change patterns of trade and transport, depending on the levels of future eco taxes.

Fuel Price Risk Management

There is now an increasing array of sophisticated financial instruments designed to help provide certainty for companies that are working in the transportation business. Given that energy costs are such a significant component of the operating costs of any transport business, companies need a degree of certainty so that they can offer stable prices to customers—while the business is not exposed to any undue degree of risk. The financial instrument used to help stabilize fuel prices is known as a “hedge.” A hedge is a way of investing to offset any potential future losses or gains. By using financial instruments such as commodity swaps and options, heavy consumers of fuel are able to establish capped or fixed fuel prices—which assists with business planning, forecasting, and accounting.

Comparing Fuel Options

It is challenging to make comparisons between the economics of different fuel types in vehicles. One measure that can be used is miles per gallon gasoline equivalent, expressed as MPGe or MPGge. The metric equivalent of this would be “kilometers per liter equivalent.” Here, vehicles using alternative energy sources are compared with the measure of efficiency commonly applied to fossil fuel vehicles—“miles per gallon.” In the United States, where this measure is applied by the Environmental Protection Agency, an equivalence figure of 33.7 kWh per gallon is used to express the energy content of petrol/gasoline to enable comparisons to be made between electric and conventional vehicles. Through this measure, and knowledge of the costs per gallon of fuel and kWh of electricity, it is possible to make accurate cost comparisons when evaluating the energy costs of a range of different vehicles.

New Transportation Energy Sources

There is a need to transition away from fossil fuels to newer transport energy technologies. Presently, electricity is used to power some railway lines and

other transport infrastructures with fixed routes, such as urban trams and trolleybuses. Here the electricity is conveyed to the vehicle by rail or overhead catenary wire. The electricity to supply these applications will come from a variety of primary energy sources, depending on the location and the mix of technologies producing grid energy. Electric motors are very efficient across a range of speeds. If the power is coming from nonrenewable sources, then fuel will be burned in a thermal power station. There are losses in generation and distribution of the electricity—but even considering these, the efficiency of the electric motor means that the cost of energy for running these vehicles is still lower than their fossil fuel counterparts. Here, in economic terms, the cost of the energy required to run alternative fuel vehicles is often much lower than fossil fuel vehicles. However, the challenge is that the capital cost of investing in the initial technology and/or infrastructure required to support the technology may be high and affect the overall economics of the transport solution.

Making electric vehicles that are not tied to fixed infrastructure is more challenging. There are additional losses involved in storing energy and transporting the weight of batteries.

Some low-speed, low-range applications can use very simple battery chemistries, such as the commonplace lead-acid battery, which is comparatively cheap. In some transport applications, this simple electric vehicle technology is appropriate. For higher performance transport applications, more sophisticated battery chemistries are required. This adds significantly to the purchase cost of the vehicle. The high cost of batteries for energy storage adds significantly to the vehicle purchase price and may also require periodic replacement as batteries degrade. This is offset by savings in the energy costs over the vehicle’s lifetime.

Another potential avenue for providing energy to vehicles is in the form of hydrogen and fuel cells. Hydrogen generates only water at the point where it reacts with oxygen in the air. Again, this is an early-stage technology. The cheapest way to produce hydrogen is steam reformation. This process is presently used internationally to produce hydrogen commercially. This does, however, come with the disadvantage that as a by-product of the process, methane used as a feedstock is converted into hydrogen but the carbon from the process ends up

as carbon dioxide. So while this is the cheapest way to produce hydrogen, and no carbon emissions are produced at the point of use, there are still carbon emissions resulting from the process.

One possible alternative is to produce hydrogen from electrolysis of water. This would be a much more expensive process. There is the potential, however, to use “off peak” electricity in the middle of the night or at times of low demand to produce this hydrogen. This could help make use of “surplus” energy and keep the costs of producing hydrogen down.

To incentivize the use of electric vehicles, many municipalities and businesses are providing free electric charging stations. As the energy for powering electric vehicles is so cheap, the benefits accruing to a business—through retention of customers, more time spent in store browsing, etc.—more than offset the cheap cost of the energy supplied free.

As alternative vehicles are in the very earliest stages of development and market penetration, the mechanisms used to price the energy they consume are not well developed. There are many interesting debates, for example, might energy used for powering electric vehicles be charged at a different rate from domestic energy? Furthermore, through demand-side management measures, there is the potential for electric vehicles to act as a useful tool for balancing the variable energy output of renewable sources—in future energy scenarios where a much greater proportion of grid energy comes from these sources.

One solution that has been considered for a future transport energy scenario is the idea of “smart grids.” Here, in addition to electricity being supplied by the grid, there is also information about the availability of energy from the grid. Pricing is potentially dynamic, creating a market of supply and demand. When there is an abundance of renewable energy and insufficient demand, the price of the grid electricity drops. Devices interacting with the grid could be programmed to only use cheap electricity below a certain tariff. Thus, if there is suddenly a spike in demand, or a drop in supply, devices programmed to only buy off peak electricity will disconnect from the grid. For an application like charging an electric vehicle, this will have no noticeable impact to the customer (for example, if he/she is charging a car overnight) but manifold benefits for the grid and cost of providing energy.

At the moment, as governments around the world seek to encourage alternative vehicles, the energy that powers them is often taxed at rates that incentivize use. However, as market penetration is achieved and alternative fuel vehicles become commonplace, it is inevitable that taxation regimes will change and these will be reflected in the energy costs of powering these vehicles.

Energy Policy Act of 1992

The Energy Policy Act of 1992 (EPA 1992) represents one of the most significant pieces of legislation in the area of energy policy and law in the United States. It promotes energy efficiency and the use of renewable energy. It is organized in 27 titles addressing various elements of energy policy

and law relating to, among other things, energy efficiency in buildings and industrial sites, natural gas, high-level radioactive waste, and coal policies. The overall goals of the act relate to the ambitions to reduce the reliance on costly oil imports; conserve and more effectively use available energy; reduce the use of traditional, petroleum-based fuels in motor vehicles; increase competition in alternative fuels markets; address global warming; implement solutions relating to nuclear waste; and secure sufficient oil reserves.

Definition and Designation of Alternative Fuels.

The EpAct 1992 provides a nonexhaustive list of substances that can fall under the definition of alternative fuels in section 301(2). On one hand, these can be alcohols, such as methanol or denatured ethanol or mixtures of alcohols with gasoline, natural gas, hydrogen, coal-derived liquid fuels, liquefied petroleum, and other fuels. The proportion of alcohols should be at 85 percent or more and, in certain circumstances, determined by the secretary of energy's rule, can be at 70 percent or more. On the other hand, the definition contains a degree of flexibility as it can include, when determined by rule by the secretary, any other fuel that is "substantially not petroleum and would yield energy security benefits and substantial environmental benefits" (the three criteria).

The inclusion of the additional fuels to the pool of alternative fuels is made possible through sending a petition to the U.S. Department of Energy (DOE). The DOE has considerable discretion to determine whether the proposed fuel will be classified as an alternative fuel on the basis of the application. The discretion stems from the fact that the decision-making process is highly resource intensive. The applicant must prove that the fuel meets the three criteria with extensive high-quality data. Further, the supporting material sent by the petitioner is published online and made available to the general public.

As of 2013, the DOE was still in the process of considering Rentech, Inc.'s petition to designate diesel fuel made from natural gas using the Fischer-Tropsch process. The petition was submitted in July 1999, thus providing an example of how complicated and time consuming the process of designation under s. 301(2) of the EpAct 1992 can be.

Covered Fleets

The act imposes certain requirements on the "covered fleets" that are addressed to state entities and alternative fuel providers' fleets. State entities, including state universities and colleges, can report as a single entity or on an agency basis. The alternative fuel providers should engage principally in producing, storing, refining, processing, distributing, transporting, and importing or selling alternative fuels. The definition also includes those producing, transmitting, importing, or selling electricity and those who produce or import petroleum with significant revenue generated from producing alternative fuels. First, it is important to ascertain whether a given fleet is a "covered fleet"; second, ensure that the operators or controllers of the covered fleets meet the requirements specified in the act. The paragraphs immediately below provide an explanation relating to the first question, followed by a description of specific requirements that must be met by covered persons operating the covered fleets.

Both state entities and alternative fuel provider fleets are subject to the same test consisting of three elements. First, they should own, operate, control, or lease at least 50 motor vehicles within the United States. Under section 301(9) EpAct, certain vehicles are excluded from the count, for example, law enforcement vehicles; emergency vehicles; vehicles used for product evaluations, tests, or demonstrations; nonroad vehicles, including farm and construction vehicles; and vehicles kept for lease or rental to the general public. Second, 20 out of at least 50 qualified vehicles must be used primarily within a single metropolitan area or a consolidated metropolitan statistical area with a population of 250,000 as of 1980. Third, the same 20 motor vehicles must be centrally fueled or "capable of being centrally fueled." The DOE sheds more light on the capability issue by stating the following:

. . . [v]ehicles are considered capable of being centrally fueled if they are capable of being fueled at least 75 percent of the time at a location that is owned, operated, or controlled by any fleet or under contract with that fleet for fueling purposes.

As of May 3, 2012, there were 296 covered fleets listed by the DOE. These included state entities

such as Arizona State, specific agencies such as the Texas Department of State Health Services, universities such as Pennsylvania State University, and private alternative fuels, electricity, and petroleum companies.

State Agencies: Acquisition Requirements.

State agencies may take possession of new motor vehicles, including used vehicles, from time to time. When the state fleets are covered by the act, the operators must ensure that 75 percent of newly acquired low-duty vehicles must be alternative fuel vehicles (AFVs). The calculation is fairly straightforward: if a state entity decides to acquire 205 vehicles in a given year and five of them are excluded vehicles (for example, nonroad cars) then 150 newly acquired vehicles must be AFVs. On occasion, the state entities may not be able to meet the acquisition requirements. They can apply to the DOE for an exemption, supported with evidence, after exhausting all possible avenues to satisfy the requirements. The DOE may grant such an exemption, which will only apply to a given model year and will not be renewable. The state entities may also apply for an exemption based on the unavailability of appropriate alternative fuels for their AFVs or on the basis of financial hardship. In all circumstances the DOE will consider such applications on a case-by-case basis. The acquisition requirement is accompanied with a reporting duty. Each operator of the covered fleet must submit an annual report using predetermined forms on the status of compliance to the DOE. The operators enjoy considerable discretion whether to submit one report as a single state entity or separate reports by each agency in the state.

**Alternative Fuel Providers:
Acquisition Requirements**

Similar requirements apply to the alternative fuel providers' covered fleets, albeit with certain differences. Thus, the threshold is significantly higher and such operators must ensure that 90 percent of newly acquired low-duty vehicles must be AFVs. The operators may choose to comply with the acquisition requirements as a single entity, including associated entities and subsidiaries, or as a number of separate entities. There is also some flexibility for the companies that merge or split in a given year of compliance with the acquisition requirements. In such circumstances, the companies may choose

to comply and report as a single entity or as a set of individual entities. As with the state entities, the businesses may apply for an exemption, supported with evidence, to the DOE in a given year. If granted, the exemption is valid for one year only.

Alternative Fuel Vehicle Credit Program

Overall, the compliance with the act is on an annual basis, which is reflected in the reporting requirement. However, the operators are allowed to take account of the longer time horizons in a form of an AFV credit program. The purpose of this scheme is to inject some flexibility without undermining the overall goals of the act to minimize the dependence on traditional fuels. Thus, the covered fleets earn credits when exceeding the statutorily required number of acquisitions of AFVs in a given year or acquiring the vehicles earlier. One vehicle is worth one credit, and DOE keeps a credit account for each covered fleet and presents them with an annual credit statement. The credit program functions similarly to other trading schemes. Thus, the entities can exchange, sell, buy, or give away the credits in the present and in the future. The traders should complete a transaction form and send it to the DOE within 30 days of the transfer date.

**Executive Order 13149:
Alternative Fuel Vehicles**

It became clear that the Energy Policy Act of 1992 was significantly flawed because it focused on the acquisition of AFVs and not on the use of alternative fuels. To reconcile this problem, in April 2000 President Bill Clinton issued Executive Order 13149 addressed to federal agencies. Section 201 of the order states the following:

. . . each agency operating 20 or more motor vehicles within the United States shall reduce its entire vehicle fleet's annual petroleum consumption by at least 20 percent by the end of [financial year] 2005, compared with [financial year] 1999 petroleum consumption levels.

The agencies should prove compliance with the requirement through a development of performance strategies. They can adopt measures suggested in the order such as the use of alternative fuels heavy-duty vehicles alongside the low-duty vehicles, a reduction in overall mileage. The agencies

can also develop their unique performance strategies with innovative measures and goals to meet their particular needs. All agencies should increase the average fuel efficiency of their cars and ensure that alternative fuels are used for the majority of the fuel requirements of the alternative fuel vehicles. In this sense the order complements the requirements entrenched into the EAct 1992.

Alternative Method of Compliance

The Energy Policy Act of 2005 (EAct 2005) provided for an additional alternative method of compliance with the acquisition requirements under EAct 1992. Thus, the alternative compliance allows the covered state entities to apply for waivers from the standard compliance acquisition requirements. Instead of focusing on the acquisition of alternative fuel vehicles, the entities that were granted the waiver focus on the reduction in the use of petroleum-based fuels. The participation is based on an annual basis. The entities interested in participating in the alternative compliance in a given year must submit an application to the DOE. The application should contain information demonstrating how the organization plans to achieve a reduction in the use of petroleum that will be equal to the predicted use of the alternative fuels during that year. To calculate the balance, the entity should take account of the existing fleet of AFVs and the AFVs that the organization would have to acquire during the application year. The application should contain reliable data, all of which will be verified by the DOE before granting the waiver.

Apart from the general flexibility, the alternative method can address certain problems that the entities may face in satisfying the standard compliance with EAct 1992. Some entities may have to apply for exemptions if the alternative fuels are not available in their area. The alternative compliance method allows those entities to use the waiver in lieu of the exemptions, which are granted on a case-by-case basis and thus unpredictable. Further, the entities may also calculate the reductions in the use of traditional fuels by taking into account the results achieved by the heavy-duty vehicles. In certain circumstances the applicant may also include the nonroad vehicles into the overall calculation. The DOE issues a decision whether to grant the waiver within 45 days from obtaining all necessary and verifiable information in the application. If

the decision is positive, the entity should carefully implement the reduction plan by keeping records of all measures. Such entities must also submit annual reports to the DOE demonstrating compliance with the reduction plan.

Provision of Information

The EAct required the secretary of energy, in consultation with the relevant federal agencies and experts, to establish a public information program. The intent of the scheme is to familiarize the general public and the fleet operators with the costs and benefits of using alternative fuels and AFVs. The government should provide verifiable and accurate data that can assist the public in choosing the appropriate fuels. The relevant information can also be provided through the effective labeling. At present, the DOE maintains a number of Web sites consisting of much information on alternative fuels. It also runs workshops and designs, codesigns, or supports a number of programs such as Clean Cities, State Energy Program funding, National Clean Diesel Campaign, Clean School Bus USA, Clean Ports USA, and Clean Construction USA. In terms of labeling, the AFVs and fuel dispensers must contain labels providing appropriate information to allow consumers to make an informed decision about the purchase. Thus, for example, the labels attached to the fuel dispensers must specify the name of the fuel and the fuel rating.

Compliance Data

In 2000, less than half (seven) of 18 covered federal entities met the 75 percent acquisition requirement. It was reported that nine agencies increased their reliance on traditional petroleum fuels between 1999 and 2000. Two years later nine agencies failed to satisfy the 75 percent requirement; the figure dropped to five in 2003. In 2007 the entities had a first opportunity to apply for the alternative method of compliance. In that year the overall compliance with the standard method was reported at 97 percent. In 2011 (reported in 2012) all 293 covered entities complied with either with the standard or the alternative methods. Two hundred eighty fleets chose to work with the standard method and 63 percent of them exceeded their 2011 acquisition requirements. The covered fleets that chose to work with the alternative method exceeded their reduction targets by 80 percent.

EPA 1992 and Clean Cities

The above-described mandatory requirements have been amended and developed over time to embed flexibility into the acquisition schemes. Flexibility is required because, with rapidly advancing technology and economic cycles, the command and control regulation proves largely ineffective. Yet, section 505 of the EPA 1992 consisted of a provision titled “Voluntary Supply Commitments.” The government was originally required to identify voluntary commitments in geographically diverse parts of the United States.

The scheme aimed at linking fuel suppliers, owners of 10 or more vehicles, and suppliers of alternative fuels. Thus fuel suppliers could “make available to the public replacement fuels” and provide for “the construction or availability of related fuel delivery systems”; owners of the vehicles could be encouraged to acquire AFVs and alternative fuels; whereas the suppliers of AFVs could “make available to the public alternative fuelled vehicles and to ensure the availability of necessary related services.” Section 505 provided a foundation for the Clean Cities Program, which has expanded significantly since its establishment in 1993.

As of 2006 there were about 90 coalitions that brought together approximately 4,400 stakeholders. The coalitions covered a population of nearly 180 million citizens, that is, about two-thirds of the overall U.S. population. Since then the scheme has grown significantly. As of 2013 there were nearly 100 Clean Cities coalitions across the United States bringing together about 13,000 stakeholders from public and private sectors. Today, the coalitions include about 228 million people, which is approximately 74 percent of the overall U.S. population.

The stakeholders include the aforementioned owners and suppliers and, in addition, local governments, national laboratories, state and federal agencies, and other organizations. The coalitions stimulate collaboration and exchange of information creating opportunities for networking and dissemination of technical information. They also facilitate adoption of new technologies in the regions. The regional coalitions are complemented with and supported by the national partnerships, including National Clean Fleets Partnership, National Parks Initiative, Electric Vehicle Infrastructure Training Program, and Advanced Vehicle Technology Competitions.

There are ongoing possibilities for establishing further coalitions. The prospective applicants should have an active network of stakeholders, a clear organizational structure and goals, an identified coordinator, and funding. The DOE Web site provides up-to-date information as to available funding programs.

Electric Motor Vehicles

Title VI included a number of provisions aimed at promotion of and encouragement to use electric motor vehicles (EMVs). These provisions have been complemented with and extended by other statutory and nonstatutory initiatives. The sections below concentrate on explaining the original provisions.

Under Subsection A the government was required to establish an EMV demonstration program with an allocated funding of up to \$50 million. The primary goal of the scheme was to foster the development of electric vehicles and evaluate the performance of such vehicles. The secretary of energy was required to “solicit proposals to demonstrate electric motor vehicles and associated equipment” in metropolitan areas. The prospective proposers of the demonstrations had to provide certain information in their applications, such as description of the vehicles, the suggested users of the electric vehicles, the number of vehicles to be demonstrated, and their life cycle costs. The chosen proposers could demonstrate and sell their vehicles in specified areas. Crucially, the proposers could offer a discount to the buyers or leasers and the government would provide the proposer with a reimbursement. The maximum reimbursement was established at \$10,000. In return for the discount, the users of the electric vehicles agreed to provide the government and the proposers with information regarding the operation and performance of the vehicles.

Subtitle B of Title VI allocated up to \$40 million for the development of infrastructure and supporting systems for electric motor vehicles. Under section 622 the secretary was required to solicit proposals from persons willing to engage in cost-shared research; development, proportion, and application of an infrastructure; and support systems programs. The projects could include the following: servicing electric vehicles, installation of charging facilities, development of health and safety measures, guidelines concerning battery charging and emissions,

information exchange programs, and other initiatives deemed necessary by the government.

Revenue Provisions

Tax provisions play an important role in encouraging the use of alternative vehicles as opposed to traditional fuels in transportation. In the 1980s the U.S. government under the Ronald Reagan administration was not in favor of using tax law to promote a greener economy. It was believed that a free market approach and especially high oil prices would encourage the public to use the alternatives. The approach was not fully successful as, at the end of the decade, oil prices were very low. The Energy Policy Act 1992 was a major legal instrument that marked a move away from the free market approach toward a more interventionist course in relation to tax provisions.

Fringe Benefits for Employers

Section 1911 regulated so called qualified transportation fringe, that is, means of work-related transportation and parking facilities that were encouraged through tax exemptions. The qualified transportation fringe included (1) "transportation in a commuter highway vehicle" between the place of work and the employee's residence; the vehicle should have at least six spaces for passengers; (2) "any transit pass" that entitles an employee to use private or public mass transportation or a commuter highway vehicle; and (3) qualified parking near the place of work or near the location from which the employee catches the qualified vehicle to commute to work. The qualified parking explicitly excluded parking spaces on or near the residence of the employee. It is important to note that the EAct 1992 expanded the meaning of "transportation fringe" as prior to 1992 only qualified parkings were regulated as fringe benefits.

The employer could provide benefits exempt from tax to the employee for the purpose of using the above means of transportation and parking. The amount of benefits was capped at \$60 per month for the use of commuter highway vehicles and transit passes, and \$155 per month for the use of the qualified parking.

Deductions

Section 1913 provided a range of incentives for the individual or business taxpayers in relation to the

purchase of clean fuel vehicles and electric vehicles and for the installation of refueling properties. Taxpayers could benefit from deductions of between \$2,000 and \$50,000 in the year in which they put a clean vehicle into service and \$4,000 for purchasing an electric vehicle. They could benefit up to \$100,000 for placing a refueling property into service during a taxable year.

Conclusion

The Energy Policy Act of 1992 was an important and complex piece of legislation that dealt with, among other things, energy issues relating to transportation. This article has described the core provisions whose aim was to encourage the use of alternative fuel vehicles, electric vehicles, and the installation of the appropriate support facilities such as refueling stations. Some of the provisions were mandatory and others voluntary, resulting in a formulation of mutually reinforcing pillars. Many of the provisions have been amended by subsequent legislation such as the Energy Policy Act of 2005; thus, the reader is urged to analyze the EAct 1992 in the context of later legal and policy mechanisms.

How successful have the EAct 1992 provisions in encouraging the use of cleaner energy in transportation? A 2010 report prepared for Congress by the Department of Energy is somewhat cautious in pronouncing a big success:

Overall, the EACT programs displace hundreds of millions of gallons of petroleum annually. This amount, however, is less than one percent of the approximately 175 billion gallons of petroleum used on the nation's highways each year.

Energy Policy and Conservation Act of 1975

On December 22, 1976, President Gerald Ford signed the Energy Policy and Conservation Act (EPCA) into law (P.L. 94-163). The act (S. 622) was the culmination of a year-long struggle between the executive and legislative branches to develop what the president called "the basic framework of a national energy policy." The debate over that policy had been ongoing for several years in response to concerns over America's dependence on foreign oil and the damage that fossil-burning fuels were exacting on the environment. Support for developing alternative sources of energy continued to rise during and after passage of the EPCA, and the act was eventually amended to focus on that aspect of energy policy. Upon signing the bill, Ford bemoaned the fact that U.S. dependence on foreign oil had continued at "an intolerable rate" following the oil embargo of 1973. The most far-reaching aspects of the EPCA may have been the creation of Corporate Average Fuel Economy (CAFE) standards, which mandated the manufacture of more fuel-efficient cars and light trucks, the expansion of

U.S. oil reserves, and empowering the president to deal with oil crises.

While unhappy with the final version of the bill, the president recognized that establishing a framework for energy policy was more important than continuing to engage in political squabbles. Ford cited three major reasons for signing the bill. First of all, the EPCA allowed him to continue working toward meeting his midterm goals for energy independence as laid out in his first State of the Union address. It accomplish this action through creating a strategic storage system, mandating the conversion of oil- and gas-fired plants to those that burned coal, implementing energy efficiency labeling, establishing emergency authority for dealing with any future oil crises, and empowering the government to fulfill agreements with other oil-consuming nations.

The second reason that Ford agreed to the compromise set forth in the Energy Policy and Conservation Act of 1975 was that it established the groundwork for phasing out of controls on domestic oils, thereby encouraging additional oil exploration and development within the United States. Ford promised that all controls on domestic oil prices would be phased out within 40 months of the bill's becoming law. Ultimately, Ford signed the bill because he recognized that vetoing it would have resulted in no action being taken in the areas of energy policy and conservation. Ford did acknowledge that additional legislative action would be required to establish natural gas policies to deal with immediate shortages and the need to increase supplies of natural gas in the United States. He urged Congress to act on his proposal to allow oil from the naval petroleum reserves to be used to promote energy efficiency and stimulate the commercial development of synthetic fuels.

Oil Embargo

Since the Industrial Revolution, Americans had been burning coal and oil in massive amounts. While the use of such fuels reduced labor and increased the standard of living, it had also resulted in a mounting dependence on imported petroleum products. On October 18, 1973, the Organization of Petroleum Exporting Countries (OPEC) initiated an embargo of Arab oil in order to hit back at the United States for supporting Israel during the Arab-Israeli conflict (1969–76). OPEC was created at the Baghdad Conference in September 1960 by

A gas station owner stands by his empty pumps in 1973. That year, an embargo coordinated by OPEC nations resulted in high gas prices and shortages, as well as unemployment and inflation. The crisis cost the U.S. economy an estimated \$10 billion.

the founding nations of Iran, Iraq, Kuwait, Saudi Arabia, and Venezuela as a means of coordinating policy among oil-exporting nations and regulating the petroleum-export industry. The oil embargo continued until March 1974.

The impact of the embargo on the United States was immediate. Many people were forced to wait in long lines at service stations to fill their gas tanks, and a large number of stations began closing on Sunday to keep from running out of gas. The price of foreign oil rose almost 400 percent between October 1, 1973, and January 1, 1974, rising from \$3 per barrel to \$11.65 per barrel. The price at the pump skyrocketed from 35 cents a gallon to 56 cents a gallon. The impact was also felt far beyond the gas tank. Over the course of a year, utility bills rose by

nearly \$500. American production rates declined at the same time unemployment and prices rose. Inflation climbed from 6.2 percent in 1973 to 11 percent in 1974 before dropping to 9.1 percent in 1975. According to figures released by Secretary of State Henry Kissinger, the oil embargo cost the United States 500,000 jobs and more than \$10 billion in costs stemming from inflation. At the same time the American economy was taking a nosedive, oil companies were reporting huge profits, which rose as much as 82 percent between 1972 and 1973.

Devising Energy Policies

Under considerable pressure, Congress worked with President Richard Nixon to deal with the oil crisis. The Federal Energy Administration and the Energy Research and Development Administration were established to coordinate energy policy and activities. After Nixon resigned in August 1974 amid the Watergate scandal, Vice President Gerald Ford was elevated to the presidency. Anxious to help repair the damaged reputation of the Office of the President while dealing with the ongoing energy crisis, the Democrat-controlled Congress expressed its willingness to work with President Ford on developing a new energy conservation policy.

By January 1975, Ford had sent a plan to Congress, calling for cutting energy consumption and stimulating the economy through increasing the price of imported fuels by levying a \$3 per barrel import fee and lifting federal controls put in place by his predecessor. However, some congressional Democrats preferred taxing gas directly at the pump. Regional and political differences led to heated debates in Congress, resulting in what Jim Wright (D-Texas) called “a farcical comedy of frustrations.” The EPCA was introduced in the Senate by Henry M. “Scoop” Jackson, a Democrat from Washington State.

The House version of EPCA, the Energy Conservation and Oil Policy Act of 1975 (H.R. 7014) offered a more comprehensive energy policy than that proposed by the Senate. However, Republicans on the conference committee refused to sign it. In response to these regional and party differences, a number of compromises led to passage of the Energy Policy and Conservation Act of 1975, an energy plan that fully satisfied no one but did manage to steer the United States toward the development of new energy policies.

Two major provisions of the Energy Policy Conservation Act of 1975 were the creation of the Energy Research and Development Administration and the extension of insurance for the nuclear power industry in the United States. Congress removed the oil and gas depletion allowance supported by Ford and the Republicans from the final version the bill, which meant that oil companies were required to pay an additional \$2 billion in taxes.

Agencies and Standards

The Energy Policy and Conservation Act of 1975 expanded the authority of the Federal Energy Administration (FEA), assigning the agency responsibility for overseeing the mandated switch from oil to coal in major power plants and fuel-burning installations. The administrator of the National Highway Traffic Safety Administration was given authority to grant loans of \$30 million to \$750 million to encourage the development of underground coal mines. No more than 20 percent of such loans were to be used in the development of new high-sulfur coal mines. The secretary of the interior was charged with establishing rules governing bidding for rights to develop crude oil, natural gas, and natural gas liquids within the Outer Continental Shelf.

All automobiles manufactured or imported after 1977 were required to meet Corporate Average Fuel Economy (CAFE) standards. Those standards required that all such automobiles achieve the standard of operating at energy-efficient levels of at least 26 miles per gallon by 1985. The National Highway Traffic Safety Administration of the Department of Transportation was assigned authority to regulate CAFE standards.

Another provision of the Energy Policy and Conservation Act of 1975 launched a federal energy testing and labeling program that applied to all major consumer products manufactured in the United States. The EPCA gave the federal government the authority to audit any person or company that was required by federal law to submit energy information to any government body except the Internal Revenue Service. All vertically integrated oil companies were required to verify any information submitted in reports.

Oil Reserves

The EPCA also created a national strategic petroleum reserve of 1 billion barrels of oil and petroleum

to protect the United States for up to three months in case of another oil embargo. FEA was required to submit a Strategic Petroleum Reserve Plan to Congress by December 15, 1976. The plan was to include an environmental assessment and provide details on storage facilities, including costs, predicted impacts on petroleum prices, and plans for distributing the reserves whenever it became necessary. A plan for establishing an Early Storage Reserve was to be submitted on Congress within three months of passage of the EPCA, and Early Storage Reserves were to be set up in existing facilities in order to meet the needs of individual regions. Further, a Regional Petroleum Reserve was to be established within each Federal Energy Administration region. Under the leadership of the administrator of the FEA, an Industrial Petroleum Reserve was to be created by requiring all companies that imported petroleum products to store up to 3 percent of amounts imported or refined during the previous year. Congress appropriated \$100 million to be used in developing the Strategic Petroleum Reserve Plan and authorized necessary appropriations for the implementation of the Early Storage Reserve.

Presidential Standby Authority

The EPCA also gave the president of the United States the authority to control the flow of energy supplies. In order to do this, the president was given authority to restrict exports of energy supplies and energy-related items; oversee the allocation of scarce energy supplies; require an increase in oil and gas production; demand that refineries adjust proportions of fuel oil and refined products produced; and mandate the accumulation, maintenance, and distribution of oil and petroleum inventories at designated levels. While existing price controls on domestic oil remained in place until 1979, the act provided for those controls to be phased out, eventually being encompassed under the president's standby powers. Domestic oil prices were immediately rolled back to no more than \$7.66 per barrel.

The president's standby powers were to be used only in the event of an oil emergency or when necessary to fulfill the obligations of international agreements. The standby powers included the authority to initiate mandatory conservation measures and gas rationing. Both were subject to review by Congress. The president was required

to submit energy conservation contingency and rationing contingency plans to Congress within 180 days. Enactment of such plans was to be effective for no more than nine months, but rationing could be rescinded by the president at an earlier date. When exercising standing authority in the area of energy conservation, the president was required to inform Congress of the potential economic impact of such a plan, including its effects on major industrial sectors, employment, consumer prices, and the potential for anticompetitive effects. In the eventuality of imposing a rationing contingency plan, the president was required to submit a plan that prioritized the use of gas and diesel fuel according to classes of end users. Local boards were to be established to deal with petitions and the need for reclassification.

The EPCA was amended in 1988 by the Alternative Fuels Act. In this act, the focus became the development of alternatives to fossil fuels, such as ethanol, methanol, natural gas, liquefied petroleum gas, hydrogen, and electricity. This act also mandated the use of alternative fuel-burning vehicles in the federal fleet.

Environmental Impacts

Like all forms of anthropogenic activity, transportation is accompanied by environmental impacts. The vast majority of transportation is based on the burning of fossil fuels. Exhaust emissions represent a major contributor to environmental degradation in the form of noxious gases, toxic compounds, and global warming. Altering the landscape and changing local land use to make way for a highway or airport can fragment ecosystems and destroy habitat. Facilities that support transportation from manufacturing to maintenance tend to be coupled with hazardous materials and waste that are harmful to the biotic community. Even loud noises from a train or jet airplane can be detrimental to the health of humans and wildlife. Until transportation breaks its bond with fossil fuels, the environmental impacts of this industry will continue.

Highways

Travel by highways is still the prevailing mode of transportation in the United States and has negative effects from roadkill to vehicle emissions. Road construction and maintenance requires the use of land that can potentially impact the environment through the disruption of natural habitat, modified hydrology, and contaminated runoff. While much of the nation's highway construction has occurred over decades, the impact on many habitats can still be felt in the form of fragmentation. In expanding urban areas road construction is ongoing and, depending on the sensitivity of the habitat, can have

significant consequences for local ecosystems such as wetlands. These wetlands may be made up of marsh, swamp, or mangrove and are beneficial for controlling floods and supporting species diversity. Construction site runoff can contribute to higher erosion rates accompanied by increased sedimentation, which can endanger aquatic habitats. Pollutants washed from roads can enter neighboring streams and lakes, affecting water quality. Repair shops, service stations, and maintenance facilities are sources of pollution in the form of gasoline, oil, and dirt runoff that enter waterways through the sewer system. Additionally, stormwater runoff is prevented from infiltrating paved surfaces and thus cannot replenish underground aquifers.

In large urban areas, 90 percent of the carbon monoxide (CO) and 50 percent of the ground-level ozone (O₃), a major component of smog, is attributed to vehicle exhaust. Automobiles emit nitrogen oxides (NO_x) and sulfur oxides (SO_x), which contribute to the formation of acid rain as well as volatile organic compounds (VOCs) and particulate matter, which are carcinogenic. It is estimated that the annual number of premature deaths in the United States due to vehicle emissions is about the same as the number of deaths each year from traffic accidents. Overall, automobile exhaust can adversely impact the environment by damaging forests, grasslands, and croplands. Perhaps the most insidious emission in vehicle exhaust is carbon dioxide (CO₂). CO₂ is the primary greenhouse gas that causes global warming. Approximately one-third of the CO₂ released in the United States is from the transportation sector and nearly one-quarter of this total comes from motor vehicles. The current global level of CO₂ is 394 parts per million (ppm) with an annual rate of increase of 2.15 percent. CO₂ emissions from the transportation sector have risen each year by approximately 2 percent since 1990. Carbon dioxide represents 95 percent of all the greenhouse gases released by the transportation sector, which includes methane, nitrous oxide, and various refrigerant compounds.

Railways

As a result of fossil fuel combustion, hazardous material spills, and noise pollution, rail transport can seriously impact the environment. The majority of locomotives in the United States are powered by diesel, which generates emissions similar as other

fossil fuels. These include CO, CO₂, VOCs, NO_x, SO_x, and particulate matter (PM). Some passenger trains are powered by electricity, which is generally touted as clean energy. However, unless the generating station powering the train is using a renewable resource such as wind or solar, the same emissions associated with burning fossil fuels can have a detrimental impact on the environment.

Noise is a common environmental nuisance often associated with rail transport, whether it is the blast of a train whistle, the clatter of wheels on the rail, or the blare of the engine. Researchers have established that outdoor sound levels higher than 65 decibels are unacceptable. The typical noise level of a diesel engine is 100 decibels, and the blast of a locomotive whistle can be as high as 120 decibels. Over time, daily noise levels from passing trains have been known to trigger muscle/gland reactions, impair motor skills coordination, and cause gradual hearing loss. Some 3 percent of the population in the United States is considered to be affected by noise levels from trains that are classified as annoying.

Due to the role played by railways in the movement of domestic freight, the potential for hazardous material spills is significant. Approximately 30 percent of the tonnage transferred across the United States is carried by freight trains. These trains haul hazardous substances including poisonous gases, flammable liquids, corrosive chemicals, and even radioactive materials. In the event of a hazardous spill that is not properly contained, there can be severe damage to the environment in the form of impacts on human health, habitat destruction, water and air pollution, and the loss of fish and wildlife. The gravity of a railway spill depends on factors such as the volume and toxicity of the material, regional topography, and the makeup of the indigenous flora and fauna. While hazardous material spills may impact a small local area, these negative effects can have far-reaching environmental consequences.

Airways

The aviation industry is currently expanding at an annual rate of 5 percent and this growth trend is expected to continue in the coming years. The majority of commercial aircraft cruise at altitudes above 33,000 feet, releasing NO_x directly into the upper atmosphere, causing a decrease in beneficial stratospheric ozone and increasing levels

Deicing fluid runs off the wing of this U.S. Army aircraft at Joint Base Elmendorf-Richardson in Alaska, January 2012. As much as 80 percent of deicing fluid, which is often made up of ethylene and propylene glycol, may end up running off into the soil around airports. An estimated 12 million gallons are used at airports in the United States every year.

of tropospheric ozone that could enhance global warming. As the airline industry continues to rapidly expand, NO_x emissions, which contribute to acid rain, will continue to escalate, affecting buildings, ecosystems, and wildlife. Water vapor released from the combustion of jet fuel results in the formation of contrails. These high-altitude cirrus clouds have been linked to global dimming, a decrease in the amount of solar radiation reaching the Earth's surface. Contrails have also been implicated in the formation of stratospheric clouds that are associated with the destruction of the ozone layer.

Among the environmental impacts of aviation at the surface is the runoff from the deicing of aircraft. Ethylene and propylene glycol are common ingredients in deicing formulas and are known to cause numerous biological problems. Approximately 12 million gallons of deicing substances are used annually in the United States and it is estimated that as much as 80 percent of this fluid runs off the wings onto the tarmac and eventually infiltrates the surrounding soil. Similar to diesel locomotives, jet aircraft engines also generate high levels of noise. It is estimated that at least 9 percent of the U.S.

population experiences annoying levels of noise from aircraft, which is cited as the most detrimental environmental impact related to aviation.

Environmental Justice

Environmental justice (EJ), both a social movement and a field of inquiry, concerns itself with justice issues associated with both the distribution of environmental amenities and disamenities, as well as the processes of making decisions about the environment. In the context of transportation, EJ concerns include the distribution of transportation infrastructure and its appropriateness for residents, the distribution of the negative externalities from that infrastructure, and the associated decision-making processes.

What Is Environmental Justice?

Environmental justice emerged in the United States as a response to the unequal distribution of environmental hazards across social and geographical space; by the early 1990s, studies were finding locally undesirable land uses (LULUs) to be disproportionately located in poor communities and communities of color. The contemporary EJ movement coalesced in the 1980s after a series of key events. In 1978, after a truck driver intentionally dumped tens of thousands of PCBs on a roadside, Warren County (North Carolina), a predominantly African American community, was selected as the site for a landfill to dispose of the contaminated soil. This sparked a decades-long battle to first resist the siting of the toxic landfill and then to clean up the site.

In 1987, the United Church of Christ issued a comprehensive study of environmental justice that found minority status to be a strong predictor of LULU siting in the United States. The movement further developed in 1990 when activist and scholar

Robert Bullard published *Dumping in Dixie*, the first book-length treatment of this subject. EJ leaders from across the country met in 1991 for the First National People of Color Environmental Leadership Summit, where they laid out principles to guide the movement. While many EJ activists and groups continue to focus on LULU siting and cleanup, many also work on issues of transportation, food, education, and resource extraction, and are united by a concern for the public health and well-being of all people.

The role of transportation in environmental justice can be traced back to the civil rights movement, which responded to and engaged with transportation as a justice issue. Rosa Parks, perhaps the most iconic figure of the movement, used the public bus as a place to engage in civil disobedience. Her individual action spurred the Montgomery Bus Boycott (1955), in which African Americans stopped riding buses as a form of protest against segregated transit systems. Racial segregation on public transportation remained the norm in much of the southern United States through the 1960s when the Freedom Riders began riding interstate buses as a mode of protest against continued racist practices.

Several U.S. policies aim to address transportation concerns, environmental justice, and civil rights. Title VI of the 1964 Civil Rights Act prohibits the federal government from discriminating based on “race, color, or national origin.” Although EJ activists have attempted to use Title VI, recent court decisions have found that it can only be applied in cases of intentional discrimination, thus limiting its potential as an activist tool. In 1994, President Bill Clinton signed Executive Order 12898 on environmental justice, requiring federal agencies—including the Department of Transportation—to consider the impacts of their actions on low-income and minority communities. The Intermodal Surface Transportation Efficiency Act (ISTEA) of 1992 and its latest incarnation, the Moving Ahead for Progress in the 21st Century Act, include specific considerations of equity and fairness in allocation of transportation resources and public participation.

Uneven Access to Transit Amenities

In many urban centers, minority and low-income residents comprise the majority of public transportation riders—in 1995, 69 percent of U.S. bus

A resident of Portsmouth, Virginia, makes use of a new bike path in 2013. Minority and low-income residents often have less access to safe spaces for walking and bicycling. The path was created as part of a recent plan that took into account residents' demands for more pedestrian- and bicycle-friendly streets.

riders were minorities. Low-income and minority communities tend to rely on public transit, walking, and bicycling as transportation more than white and higher-income communities. Yet transportation funding, which is usually driven by congestion relief concerns, is heavily weighted toward roadways rather than bus and light rail systems. Even within public transit systems, there are funding disparities; cities tend to invest more readily in light rail than in bus systems, though bus systems are much more likely to serve low-income and minority residents.

In the 1990s, the Bus Riders Union formed in Los Angeles to protest the city's uneven investment in rail versus bus systems; the rail system then under construction and mostly serving white residents, was at the time consuming 70 percent of the regional transportation agency's annual transportation budget even though it met the needs of only 6 percent of public transit riders. Such uneven funding and transit access are exacerbated by the legacy of post-World War II land use practices, racist mortgage policies, freeway funding, and exclusionary zoning, all of which helped create urban cores in the United States that tend to be composed of poor and minority residents. Consequently, the spatial mismatch problem (that is, impractical distances between

where people live and work) is exacerbated in low-income and minority communities where residents rely on public transit or pedestrian infrastructure for transportation.

Minority and low-income residents may also have less access to roadways and walkways that are safe for walking and bicycling; thus African American and Latino residents are much more likely than their white counterparts to fall victim to pedestrian and bicycle-related deaths.

Negative Transit-Related Impacts

Evidence suggests that low-income and minority communities experience a disproportionate burden of the negative environmental impacts from transportation. Like other undesirable land uses, such as hazardous waste facilities, freeways often locate in low-income or minority neighborhoods due to a confluence of factors, frequently including low perceived opposition to construction, legacy of racist housing practices that led to segregated communities and disinvestment from urban cores, and low land cost. At the same time, pollutants from vehicles are often the most severe next to roads. The common air pollutants from vehicular traffic—particulate matter (PM), nitrogen oxides (NO_x), sulfur dioxide (SO₂), unburned hydrocarbons, and carbon monoxide (CO)—affect public health both locally and regionally. Many EJ studies have found that poor and minority communities are disproportionately affected by vehicle-related air pollutants and the resultant health problems, including asthma and cancer. These patterns hold true outside the United States as well; in a 2007 study of Christchurch, New Zealand, researchers Simon Kington and colleagues found that disadvantaged communities experience the highest level of pollution exposure from vehicles and that areas with high car ownership experience lower levels of exposure.

Roadway- and public transit-related light and noise pollution also often disproportionately affect these communities. While these may seem like mere annoyances, constant exposure to noise and light pollution can contribute to negative health impacts. Noise pollution can affect cardiovascular health, exacerbate health problems associated with stress, and possibly affect cognitive development in children. Light pollution may have negative effects on mood and cognition as well.

Pollution from diesel trucks has been particularly problematic, not just from truck routes but from idling vehicles. For example, in 1998, WE ACT was formed to address a multitude of environmental hazards, including six diesel bus depots, in heavily African American and Latino North Manhattan. Community groups such as WE ACT are concerned not only about the air pollution produced by idling vehicles but also about the threat such facilities provide to pedestrian safety.

Most environmental justice scholars would argue that unjust practices and processes help explain these unjust patterns of the distribution of transit amenities and disamenities. Some of these outcomes are the result of practices of the past, but some derive from decision-making processes that are undemocratic. In developing new transportation planning processes, many states and municipalities are beginning to recognize the importance of democratic, inclusive decision-making processes in creating a just transportation system.

Environmental Protection Agency

The groundwork for the U.S. Environmental Protection Agency (EPA) was laid with the passage of the National Environmental Policy Act (NEPA), which was signed into law by President Richard M. Nixon on New Year's Day in 1970. Prior to NEPA, the role of government was seen as simply the conservation of natural areas due to the efforts of men such as Henry David Thoreau, John Muir, and Teddy Roosevelt. However, as industrialism expanded, it brought with it pollution and the exploitation of natural resources.

With the advent of the first Earth Day on April 22, 1970, millions of Americans made it clear that in their view the government should not only preserve ecosystems but also punish those who abuse and degrade nature. Thus, the EPA was established on December 2, 1970, in a reorganization move that sought to unite several government agencies under one director to safeguard the environment through research, monitoring, standards, and enforcement.

The overall mission of the EPA is to protect the environment and human health. The purpose of the EPA is to ensure the United States leads the world in this endeavor by establishing and enforcing federal laws designed to fulfill this mission; that these laws are based on sound science; that all aspects of society have access to the information necessary to manage health and environmental risks; that by protecting the environment, communities and ecosystems are both sustainable and productive; and that environmental policy also protects American economic interests, including industry, agriculture, and transportation.

Automobiles

Among the earliest challenges for the EPA was bringing automobile emissions into compliance with the standards of the Clean Air Act (CAA) of 1970, which established benchmarks for national air quality. At the time, the leading source of air pollution was the automobile. The new standard for automobile emissions was impressive, calling for carbon monoxide and hydrocarbon reductions of 90 percent by 1975 and nitrogen oxide reductions of 90 percent by 1976. The head of the EPA

directly asked all foreign and domestic automakers to explain how they intended to meet these goals. The manufacturers were required to appear at public hearings to describe the approaches being examined to meet the new standards, the issues yet to be addressed, and the major hurdles in implementing the standards. The EPA went so far as to ask how much money and manpower each manufacturer anticipated using to reduce emissions by 90 percent.

The automobile industry responded with the catalytic converter, which was first installed on cars in the mid-1970s. The converters enabled manufacturers to achieve the goals set by the CAA and have since reduced pollution by some 10 billion tons. The efficiency of the catalyst is greatly reduced by lead, which had the added benefit of encouraging the development of unleaded gasoline, further reducing the health hazards associated with vehicle emissions. Today, catalytic converters are installed on more than 500 million vehicles worldwide, from motorcycles to buses, and are capable of decreasing emissions from the combustion of diesel, propane, and natural gas as well as gasoline. The passage of the CAA and the invention of the catalytic converter marked the EPA's first major victory in the battle against air pollution that continues to this day.

Railroads

Congress passed the Resource Conservation and Recovery Act (RCRA) in 1976, which was aimed at conserving natural resources and energy while reducing the hazards associated with waste disposal and the amount of waste generated. In 1984 the act was amended to require all facilities that treat, store, or dispose of hazardous waste to clean up their sites, including most railroad transportation facilities.

An environmental group, the Natural Resources Defense Council (NRDC) brought a suit against the Union Pacific Railroad and BNSF Railway in 2011, alleging that diesel exhaust is a hazardous waste that should be regulated by the EPA in accordance with the RCRA. The group claims that particulates from the locomotives have been linked to respiratory and cardiovascular disease, cancer, and premature death. The NRDC blames certain railroad yards in California for cancer rates in neighboring communities that are as much as 50 times higher than the

national average because the railroads have failed to upgrade to newer, less polluting locomotives in an effort to cut costs. The railroad companies responded that the suit was an attack on the goods industry and that rail is the most environmentally favorable mode of transportation. The lawsuit was filed in federal court, and at the time of this writing a decision had not been reached.

Shipping

The first major law aimed at controlling water pollution was the Federal Water Pollution Control Act passed in 1948. With the establishment of the EPA and a growing concern for protecting the environment and human health, the Clean Water Act of 1972 amended the 1948 law, giving the EPA the power to implement pollution control programs and prosecute those who discharge pollutants into navigable waters. The cruise ship industry is among those under the watchful eye of the EPA.

A typical cruise ship carries thousands of passengers and is literally a floating city, with the same environmental and health concerns of any community. The primary concern of the EPA in regard to cruise ships is the discharge of waste, which includes sewage, graywater, bilge water, solid waste, and hazardous waste. To address these issues the EPA has developed a cruise ship assessment report that measures the volume of each of these five waste streams, addresses ways to best manage and treat waste, examines the negative impacts associated with waste, and considers federal regulations already in place as well as those that need to be implemented in order to address cruise ship waste.

Perhaps the vilest of vessel discharges, whether it is from a sailboat or a cruise ship, is sewage. In addition to nutrients, sewage can contain solids, toxins, heavy metals, pathogens, and endocrine disrupters. As a result, sewage is capable of impacting both the aquatic environment and human health, especially in confined areas such as lakes and marinas. In addition to regulation and enforcement, the EPA recommends that vessels owners, operators, and passengers do their part to mitigate the effects of sewage discharge by minimizing the use of water, by not littering waterways, by not improperly disposing of wastes in toilets and sinks, and by recycling. These acts represent simple, effective means of reducing the sewage waste stream.

Aviation

The global demand for aviation transportation is predicted to increase rapidly in the coming years. Keeping up with this demand will require increased efficiency, an upgraded infrastructure, and compliance with the Clean Air Act. For example, nitrogen oxide (NO_x) is emitted when fossil fuels are burned and has been linked to lung disease and respiratory infection.

The International Civil Aviation Organization (ICAO) has adopted strict emissions standards for NO_x and the EPA has followed suit with new standards that apply to most large commercial aircraft that could dramatically reduce NO_x emissions by 2030 in the United States.

Likewise, leaded aviation fuel, or avgas, which is used by general aviation aircraft, is the largest source of lead contamination in the United States despite the known risks associated with lead poisoning. However, although the EPA has eliminated leaded gas from motor vehicles, it has failed to act on avgas to the dismay of environmentalists.

Similarly, the EPA concluded in 2009 that greenhouse gas emissions, including carbon dioxide (CO_2), pose a risk to the environment and human health under the Clean Air Act. The EPA established standards for cars and trucks that were challenged by various industry groups. The endangerment finding regarding cars and trucks made by the EPA was upheld by a federal appeals court in June 2012.

Nevertheless, the EPA has stated that a new endangerment finding would have to be conducted concerning greenhouse gas emissions from aircraft, which could take years to conduct. The EPA argues that aviation accounts for only 2.5 percent of CO_2 in the United States and that the agency is more concerned with larger sources of greenhouse gas pollution, such as motor vehicles.

Environmental groups are outraged at the delay but are forced to play a waiting game, knowing that eventually the EPA will have to acknowledge that aviation, like all forms of transportation based on the burning of fossil fuel, emits pollutants that are harmful to human health and the environment.

Environmental Quality Improvement Act of 1970

The Environmental Quality Improvement Act of 1970 (P.L. 91-224) strengthened the Council on Environmental Quality (CEQ), which had been created the previous year when Congress passed the National Environmental Policy Act. The director of the Council on Environmental Quality is chosen by the president and confirmed by the Senate, and the CEQ has cabinet-level status. The Environmental Quality Improvement Act of 1970 (EQIA) spelled out the responsibilities of the director. Those responsibilities include coordinating environmental policy throughout the federal government and mediating any disputes that arise when governmental bodies come into conflict.

President Richard Nixon supplemented EQIA by issuing Reorganization Plan Number 3 in which he redistributed responsibilities for overseeing different aspects of environmental protection. The Environmental Protection Agency (EPA) was created

and charged with centralizing pollution control. The Federal Water Quality Administration and the National Air Pollution Control Administration were moved from the Department of Health, Education, and Welfare to the EPA. Other agencies that held environmental responsibilities also were transferred from the Department of Agriculture and the Department of Interior to the EPA.

Although Congress passed the Environmental Quality Improvement Act of 1970 unanimously, the battle between environmentalism and “Big Business” was far from over. It continued to rage with fervor during the 1980s and heightened even further in the 1990s. With the election in 2000 of President Barack Obama, however, the CEQ was given significant support for fulfilling its intended role.

Background

In 1969, Congress passed the National Environmental Policy Act, and President Nixon signed it into law on January 1, 1970. The act was an official acknowledgement that irresponsible behavior had led to significant damage to the environment of the United States. Passage of the law set the nation on a new path in which protecting the environment became a major priority. The act also created the Council on Environmental Quality (CEQ), which oversees federal policies and programs related to the environment.

In 1962 Rachel Carson released her indictment of irresponsible behavior that played havoc with the environment, *Silent Spring*. The book provided motivation for the emerging environmental movement. Then on June 22, 1969, a rail car passing through the industrial section of Cleveland, Ohio, released a spark that sent a wake-up call around the country. When the spark reached an oil slick on the Cuyahoga River, it set the river ablaze, destroying two railroad bridges and amassing damages of some \$100,000. The oil slick was the result of decades of industrial dumping by the Republic Steel Mill. *Time* magazine featured the story of the fire on the Cuyahoga River, including a photograph of a fire that had actually occurred on the river in 1952. Cleveland became a symbol for environmental irresponsibility. However, Cleveland was not alone in degrading the environment.

Oil spills were becoming increasingly common in the United States, and beaches were also being

polluted by grounded tankers. Wildlife habitats were being destroyed in the name of progress, and the agricultural sector had polluted both land and water with DDT and other pesticides. As the 1960s with their emphasis on social revolution gave way to a new decade, the environmental movement continued to gain support.

In 1970, many Americans were up in arms over what they considered governmental disregard for the environment. Pressure mounted at the national, state, and local levels, with environmentalists urging legislatures to enact laws to improve environmental quality in the United States. The official launching of the American environmental movement is considered to be the first Earth Day, celebrated on April 22, 1970. On that day, some 200,000 people gathered at the National Mall in Washington, D.C. Smaller groups also gathered throughout the country to demonstrate the strength of the environmental movement.

Responding to the pressure, Congress and President Nixon worked together to create a national policy on environmental protection. That same year, the EPA was established to take on the responsibility of overseeing the process of forced compliance to new environmental laws.

Provisions

In the introduction to the Environmental Quality Improvement Act of 1970, Congress expressly acknowledged that the environment had suffered at the hands of humans and that population increases and urbanization had heightened that damage through pollution and environmental degradation. While stating that the chief responsibility for mitigating the negative impacts of irresponsible human behavior must necessarily reside at the state and local level, Congress accepted the responsibility of the federal government to assist in those endeavors.

A major provision of the bill concerned establishing environmental protection guidelines for all federal departments and agencies involved in public works projects. The act also bolstered the authority of the Office of Environmental Quality and assigned it responsibility for providing professional and administrative staff for the Council on Environmental Quality.

The chair of the Council on Environmental Quality was named as the director of OEQ, and the act

stipulated that a deputy director be appointed by the president and confirmed by the Senate. Responsibilities of the director included employing up to 10 environmental experts and consultants. The director was specifically assigned the responsibility to assist and advise the president on policies and programs dealing with environmental quality. In order to do this, the director was also charged with assisting other federal agencies in evaluating the effectiveness of existing policies and programs related to environmental quality, making recommendations for improving existing methods for monitoring and predicting environmental changes, promoting research into the ways that science and technology could be used to prevent or reduce the impact of damage to the environment, and assisting other departments and agencies in establishing their own standards for improving environmental quality. The director was also given responsibility for collecting, collating, analyzing, and interpreting data dealing with all aspects of environmental quality. Another provision of EQIA required the director of the CEQ to submit an annual Environmental Quality Report to Congress.

The director was instructed to work with the general public in carrying out his/her duties. EQIA also established funding for implementing the provisions of the act, and Congress appropriated \$2.126 million per year through 1979. Additional funds were appropriated to keep the CEQ functioning through 1985.

Aftermath

In the 1970s, much of the pollution affecting both air and water was caused by toxins regularly released by industrial plants. After the passage of EQIA, those plants were required to install filters that prevented pollution from smokestack and wastewater pipes being released into the environment. Small businesses and farms, on the other hand, were not always bound by environmental quality laws. In 1995, in a report for the *Congressional Quarterly*, Mary Cooper stated that despite laws mandating improved environmental quality, two out of every five Americans still lived in areas that were clogged by urban smog. One out of four also lived within four miles of a toxic dump.

One of the reasons for regression in the area, in Cooper's view, was the backlash from states following the 1990 amendments to the Clean Air Act.

Runoff from a landfill operation enters a creek that runs into the Cuyahoga River, 1973. The Cuyahoga River and Cleveland, Ohio, became a symbol of environmental degradation in the late 1960s and early 1970s as the environmental movement grew.

That act, which was passed the same year as the Environmental Quality Improvement Act, established regulations governing emissions of 189 known pollutants, mandated the use of antipollution equipment in industries, and forced automobile manufacturers to install catalytic converters in all motor vehicles.

Between 1970 and 1990, emissions of particulates declined from 25 million tons per year to less than 10 million tons per year. Other laws were passed to deal with water pollution and environmental conservation. Much of the backlash of the early 1990s resulted from the lobbying efforts of the logging, mining, and livestock industries.

When Republicans swept into Congress in November 1994, Speaker of the House Newt

Gingrich (R-Georgia) announced that the party had signed a “A Contract With America,” granting the Republican Party a mandate to rid the nation of laws passed by decades of Democratic lawmakers. Despite the fact that 80 percent of Americans identified themselves as environmentalists by that time, some Republicans attempted to undo two decades of environmental protection laws, claiming that they infringed on the rights of states and the business sector.

Within the first 100 days of taking control of both the House and the Senate for the first time in four decades, the Republican Congress considered 10 bills that contained elements that could have drastically altered the environmental landscape in the United States. Those proposed bills included the Private Property Rights Protection and Compensation Act, which would have prevented the government from enforcing environmental, health and safety protections; the Risk Communication Act, which would have allowed scientists hired by particular industries to proclaim publicly that current environmental laws were based on “bad science”; the Federal Regulatory Budget Cost Control Act, which would have limited the number of federal regulations allowed during a designated period; and the Administrative Procedure Reform Act, which would have subjected all federal regulations, included those that protected the environment, to intense scrutiny by the Office of Management and Budget (OMB).

CEQ Initiatives

Despite the 1990s attempts by ultraconservative Republicans to undo the impact of the Environmental Quality Improvement Act of 1970, along with other environmental legislation, the authority assigned to the Council on Environmental Quality under EQIA has allowed the agency to continue to carry out its responsibility to protect the environment of the United States. In 2013, one of the major initiatives being carried out by CEQ involved federal sustainability.

Federal sustainability efforts include promotion of “green government.” In October 2009, President Obama signed the Executive Order on Federal Sustainability, which instructed all federal departments and agencies to reduce greenhouse pollution; established targets for energy, water, and waste reduction; and mandated the use of environmentally

friendly products and technologies. In 2011, the CEQ worked with the OMB to generate “Sustainability and Energy Scorecards” for federal agencies for the first time in U.S. history.

Other CEQ initiatives included America’s Great Outdoors Initiative, the National Ocean Council, Recovery Through Retrofit, and Commitment to Clean Water. Launched in 2011, America’s Great Outdoors Initiative promotes efforts to guarantee a clean environment for the children of today as well as those of the future by providing parks and community areas; restoring rivers and waterways; supporting farmers, ranchers, and other landowners in environmentally responsible activities; and reinvesting revenues generated from oil and gas extraction to provide permanent protection for parks, open spaces, wildlife habitats, and recreational areas.

The National Policy for the Stewardship of the Ocean is President Obama’s plan to improve the environment of the ocean, the coasts, and the Great Lakes. Recovery Through Retrofit targets homeowners, providing them with information on energy-related issues and offering them financial incentives to take energy-saving actions. The initiative also promotes training and jobs for individuals interested in home energy retrofits. Among its many efforts to ensure clean water in the United States, the Commitment to Clean Water Initiative promotes partnerships with states, local governments, and Native American tribes to restore bodies of water such as the Chesapeake Bay, the California Bay-Delta, the Great Lakes, the Gulf of Mexico, and the Everglades.

The Council on Environmental Quality serves, along with the Office of Science and Technology Policy and the National Oceanic and Atmospheric Administration (NOAA), as cochair of Obama’s Interagency Climate Change Adaptation Task Force. Membership is comprised of representatives from 20 federal agencies. The task force is charged with developing recommendations for policies and programs designed to prepare the United States for dealing with the effects of climate change.

In response to the havoc created by the Deepwater Horizon oil spill on May 24, 2010, along the Gulf Coast, President Obama created the Louisiana-Mississippi Gulf Coast Ecosystem Restoration Working Group, which is cochaired by the

Council on Environmental Quality and the Office of Management and Budget. Senior-level officials from NOAA, the EPA, the Department of the Army, the Department of Homeland Security, the Department of the Interior, and the Department of Transportation comprise the remaining members. The group released the Roadmap for Restoring Ecosystem Resiliency and Sustainability in the Gulf area on March 4, 2010.

Equilibrium Modeling

Equilibrium modeling, which also refers to the computable general equilibrium (CGE) model or applied general equilibrium (AGE) model, is a quantitative method primarily used for economic and policy impact analysis. The method has gained increasing attention and interest in recent decades due to the development of computer technology. In the field of transportation, equilibrium modeling has been extensively used to evaluate social, economic, and environmental impacts of infrastructure investment as well as various transportation-related price policies. This introduction to equilibrium modeling covers its definition, history, data, method, model types, implementation, and limitations.

Definition

General equilibrium model is a comprehensive economic model that uses actual economic data to estimate interactions between the economy and the changes in policy, technology, or other external factors. Unlike partial equilibrium modeling, general equilibrium modeling presents a more comprehensive impact assessment because both the demand and the supply of an economy are considered simultaneously in a system of equations with linkages through price and quantity of commodities. The model is built based on the Walras-Arrow-Debreu theory of general equilibrium, with modern modifications and extensions allowing for imperfect markets. Because CGE provides clear linkages between the microeconomic structure and the macroeconomic environment, the model can be applied to simulate the interrelationships among multiple industrial sectors and markets. More importantly, it can be used to assess direct, indirect, and induced effects from the change of public policy on various economic variables such as industrial outputs, employment, prices of commodities and factors, household income, and social welfare.

In CGE models, different economic agents, such as consumer, producer, government, investment, and the rest of the world, are usually included in the general equilibrium framework. Economic linkages between agents are established and modeled through simultaneous equations. A final solution for the equation systems is found through an algorithm of calculation under the condition of a general equilibrium. To achieve the impact assessment,

a new equilibrium solution is calculated based on revised or adjusted policy inputs or parameters. Impact variations can be measured by the differences of outputs between the new equilibrium and the prior base equilibrium.

History

The first CGE model was developed by the Norwegian economist Leif Johansen in 1960. His model is distinguished from traditional economic models in that the economic behaviors of different agents are modeled separately but with coordination through prices and quantities determined by interaction of demand and supply. In the 1970s, the American economist Herbert Scarf further improved the equilibrium modeling techniques by developing a mathematic algorithm for computing solutions to numerically specified general equilibrium models. His contribution is the design of the finite convergence approach that makes the computational process of equilibrium modeling achievable in a finite numbers of steps. After 1980, interest in equilibrium modeling expanded as applied researchers began to appreciate the power of optimizing assumptions that translated broad experience into plausible predictions of particular shock effects. In addition, the development of computer technology as well as improvement of economic data collection made CGE analysis much easier than before. In terms of modeling capacity, it is now possible to conduct a CGE analysis with 500 industries, 50 regions, and 700 occupations.

By the early 1990s, CGE modeling became an established field of applied economics. Many journal articles, monographs, and books became available that facilitated knowledge expansion and further applications of equilibrium modeling. Applications of equilibrium modeling experienced several transformations: it has been expanded from single-region model to multiregional model, from static model to dynamic model, from a trade-specific model to a general model enabling the analysis of all kinds of issues, including tariff, tax policy, environmental policies, technology, and transportation.

Social Accounting Matrix

Equilibrium modeling requires a large data input. All data for the analysis has to be constructed in the form of a social accounting matrix (SAM). A SAM

represents the flows of all economic sector interactions that occur within an economy. It provides a static picture of the economy at a point in time. The conceptual structure of a SAM is illustrated in Table 1. A SAM contains information on industrial activities and commodities, which is obtained from different resources, such as an industrial input-output table, national fixed-asset accounts, government finance, import and export trade flow survey data, and other data resources.

The structural characteristics of SAM can be illustrated as Benjamin H. Mitra-Kahn from the New London School, UK, has done:

SAMs are square (columns equal rows) in the sense that all institutional agents (Firms, Households, Government and “Rest of Economy” sector) are both buyers and sellers. Columns represent buyers (expenditures) and rows represent sellers (receipts). SAMs were created to identify all monetary flows from sources to recipients, within a disaggregated national account. The SAM is read from column to row, so each entry in the matrix comes from its column heading, going to the row heading. Finally columns and rows are added up, to ensure accounting consistency, and each column is added up to equal each corresponding row.

To build a SAM for equilibrium modeling can be very challenging as the process of data collection and compilation is cumbersome. Sometimes the process can be prohibitive because some economic information may not be available. This situation is especially common for equilibrium modeling at the regional level because the input-output data of SAM is often available only at the national level. A regional-level input-output table needs to be built before the implementation of the regional-level equilibrium assessment. Industrial flows at the regional level have to be either estimated based on sector shares or collected through a regional sector survey.

Fortunately, two data alternatives have been made available by an academic institution and a commercial company for equilibrium modelers. If the analysis is conducted at a national or continental level, Purdue University’s Global Trade Analysis Project (GTAP) database is advantageous. By using input-output tables and other economic data

Table 1 Conceptual structure of a social accounting matrix

Receipts	Activities	Commodities	Factors	Households	Government	Savings/ Investment	Rest of the World	Total
Activities		Marketed outputs						Gross output

Source: Zhenhua Chen

contributed by hundreds of researchers throughout the world, a worldwide database for equilibrium modeling covers trade between more than 129 countries or regions and 57 commodities. The database contains complete bilateral trade information, transport and protection linkages, and can provide national level or aggregate multicountry SAMs using the data software GTAPAgg. The latest version—GTAP 8—was released in 2012. The data includes dual reference years of 2004 and 2007 as well as 129 regions for 57 commodities. A user license has to be purchased in order to use the GTAP database.

If the analysis only has a focus on regions in the United States, the IMPLAN database is the other alternative for equilibrium modeling. The IMPLAN

database, developed by MIG, Inc., offers region-specific data information that can be used to create SAMs at various scales from zip code to U.S. state. Unlike the GTAP database, which is sold as a whole, IMPLAN data is sold separately for different regions or scales.

Methodology

Generally speaking, an equilibrium model is a simultaneous equation system that normally consists of equations representing various economic relationships for different economic agents, such as producer, household, government, and foreign economy. Each agent interacts with others while maximizing its utility or profit under budget constraints. The analytical process includes parameter

calibration and policy simulations. In the first step, key parameters in the equilibrium model are calibrated through inverse equations based on initial economic information from a SAM. The calibration is conducted under equilibrium given all the information from a SAM representing a real equilibrium economy.

In the second step, a new equilibrium is computed through the simultaneous equations and by adopting calibrated parameters. Impacts of output are calculated after adjusting some of the input variables or the so-called policy variables. Impact changes are measured by the differences between new outputs and initial outputs. Some specific characteristics of equilibrium modeling for each economic agent are discussed below.

Household. According to Walrasian neoclassical theory, a household is assumed to maximize its utilities under budget constraints. The household utility function is the backbone of household equation systems. It can be specified in various forms based on the specific theory or the focus of research. Depending on different assumptions of substitution rates, utility functions can be specified either in a Cobb–Douglas (CD) form with constant returns to scale, or as a Stone–Geary form with constant elasticity substitution (CES). In addition, equations representing household income, household consumption expenditure, and commodity consumption need to be specified with connections to other agent blocks.

Producer. The producer is assumed to maximize profit or minimize production cost. Producers create value added through a technology specified as a production function. Depending on the specific assumption on substitution relations between factors and intermediate inputs, production functions can be represented in various forms such as CD production functions, CES production functions, or Leontief production functions (Leo). The process of production can be modeled in numerous nested structures according to the different purposes of analysis. Because equilibrium modeling is capable of differentiating different sectors in a disaggregate framework, each sector is assumed to produce one commodity and maximize its profit or minimize its cost under a nested production structure, with capital, labor, and inter-industry flows as factors of production.

Government. Government plays dual roles in equilibrium modeling. On one hand, government functions as a consumer, who allocates government expenditure to purchase various industrial outputs.

On the other hand, government collects revenue through various taxes. Equations of the government block involve both revenue equations and expenditure equations. Revenue equations normally include import tariff taxes, export tariff taxes revenue, sales taxes revenue, and indirect taxes revenue. Expenditure equations include government commodity consumption and government expenditure.

Trade. Trade is modeled using the Armington assumption under the hypothesis of imperfect substitution between domestically produced and imported goods, which can be represented by a one-level CES function. In addition, exports are assumed to be imperfect substitutes for domestically produced goods and this can be represented by a one-level constant elasticity transformation function.

Market clearing. Market clearing in equilibrium modeling includes a set of equilibrium conditions as follows:

- Market equilibrium of goods requires equilibrium on both quantity and value.
- Assuming no labor migration or institutional barriers, market equilibrium of factors requires equilibrium in the labor market.
- Equilibrium in the capital market requires that the total social investment equals total social saving.
- Government budget equilibrium requires that the budget deficit equals the difference between governmental revenue and expenditure.
- Assuming personal income only comes from wages and interest on savings, the personal balance equilibrium indicates that personal savings must be equal to the difference between personal income and expenditure.
- International market equilibrium requires that the foreign deficit represent inflows of

foreign capital, while foreign savings represent outflows of domestic capital.

In addition, in practice, a slack equation for Walras's law is usually added in the simultaneous system to check that Walras's law is not violated during the calculation. To guarantee that an equilibrium solution is achieved, certain model closure rules are applied. The total number of variables must be equal to the numbers of equations so that solutions can be found. This requires numerical specification in the modeling process.

Types of Equilibrium Models

The applications of equilibrium modeling in the transportation field are extensive. The method is able to evaluate impacts of infrastructure investment, regulations, pricing externality, and other kinds of transportation policies. Each equilibrium model is different from the others due to the differences of exogenous parameters, SAM, and structures of simultaneous equations. The modeling techniques are developed in different types of forms for different evaluation purposes. The following sections introduce three types of equilibrium models: single region CGE, multiregional CGE, and dynamic CGE.

Single region CGE. A single region CGE is a basic equilibrium model. It models a single region without considering interregional economic linkages. In general equilibrium modeling literature, the single region CGE is the most common equilibrium model. It has been widely used to evaluate various policy impacts. The single region International Food Policy Research Institute (IFPRI) model is of this kind. The model was developed by Hans Löffgren, Rebecca Lee Harris, and Sherman Robinson in 2002. One of the major model characteristics is that transportation costs were explicitly modeled as part of the trade transaction costs. This is achieved by creating a separate account in SAM that indicates transaction costs for each specific activity. The model enables assessment at the national economy of impacts due to variations of transportation costs.

Multiregional CGE. Equilibrium modeling of transportation has been widely applied in a multiregional CGE. This is because issues such as trade relations and factor mobility are very difficult to

analyze under a single region model. The structures of multiregion in equilibrium modeling with spatial dimensions enables researchers to quantify interregional flows with relations to transportation inputs, which thus facilitate the assessment of spatial impacts of transportation facilities or policies. Due to this multiregional consideration, this type of equilibrium model sometimes is named spatial CGE, or SCGE.

The examples of multiregional CGE in transportation infrastructure impact assessments are extensive. Dr. Eduardo Haddad from the University of São Paulo, Brazil, and Geoffrey Hewings from the University of Illinois, Urbana, assessed the short-run spatial impacts of transportation investment in Brazil using a multiregional CGE model called B-MARIA-27. The model includes 27 Brazilian states, eight sectors, one household in each state, regional governments, one federal government, and a single foreign consumer. By applying nonconstant returns to scale in the manufacturing production function and non-iceberg transportation costs, their model found asymmetric impacts of transportation investment on a spatial economy in Brazil.

Pingo is another multiregional CGE model developed by Norwegian scholar Olga Ivanova. The model provides forecasts on regional and interregional freight transport and evaluates its impact for the Norwegian economy. The model consists of 19 regions and 10 sectors. After calibration based on a multiregional SAM, the model forecasts impacts of transportation infrastructure based on the future values of demand.

Johannes Bröcker from the University of Kiel in Germany developed another multiregional CGE called CGEurope. The model is used primarily to evaluate spatial economic impacts of transportation networks in Europe. The model is more complex than Pingo because it contains a total of 1,341 regions and six sectors, including one sector producing transport service. Unlike the B-MARIA-27 model that treats the economy as an imperfect market, CGEurope includes separate assumptions on the trade market, where the Dixit-Stiglitz fashion of monopolistic competition is assumed while local markets are assumed to operate under perfect competition.

A similar multiregional CGE model called RAEM was developed primarily by Jan Oosterhaven from the University of Groningen in the

Netherlands. RAEM is a Dutch SCGE model that includes one household, 14 sectors, and 548 regions in the Netherlands. The model has been applied to compare and evaluate economic impacts of two different magnetic levitation railway proposals in the Netherlands at different macroeconomic scenarios. Impacts on labor mobility and economic benefits were observed in the assessment.

Dynamic CGE. All the previously introduced CGE or SCGE are static models because they can only measure impacts and model the economy at one point in time. In recent years, equilibrium modeling has been expanded from static to dynamic models. These models are more realistic, as the dynamic specification traces each variable through time. But they are more difficult to construct and solve because they require future changes to be forecast for all exogenous variables, even those that are not direct parts of the policy change. For example, the change elements can result from partial adjustment processes or from stock/flow relations: between capital stocks and investment or between foreign debt and trade effects. Despite these advantages, dynamic CGE has a potential problem. The variables that change from one equilibrium to the next may not necessarily be consistent with each other.

To deal with the inconsistent problem, the recursive-dynamic CGE model is developed, which traces out a time path by sequentially solving a static model, one period at a time. The assumption is that behavior depends only on current and past states of the economy. Alternatively, if agents' expectations depend on the future state of the economy, it becomes necessary to solve for all periods simultaneously, leading to full multiperiod dynamic CGE models. Within the latter group dynamic stochastic general equilibrium models explicitly incorporate uncertainty about the future.

Xinshen Diao, a senior research fellow at the International Food Policy Research Institute, and economist Agapi Somwaru from the Economic Research Service at the U.S. Department of Agriculture developed an intertemporal general equilibrium model to evaluate the trade reform between the United States and the Southern Common Market, including four South American countries (MERCOSUR). This is a multiregional dynamic CGE model, as behaviors of consumers and firms are intertemporally optimized. The

model helps observe significant shifts of trade diversion away from nonmember trading partners to member countries.

MONASH is another multiregional, multisectoral dynamic CGE model system that allows for different choices of the levels of sectoral and regional disaggregation. The model was developed by Peter Dixon and Maureen Rimmer from Monash University, Australia. MONASH models the Australian economy in 112 sectors by 57 subnational regions, 340 occupations, and numerous types of households. It is a dynamic model because it allows different assumptions on the economy over a 20-year period. It also allows different assumptions regarding which variables are exogenously given and which are endogenously determined, depending on the researched economic situation. Transportation sectors in this model are treated as marginal sectors where the costs are imposed on the purchase price of goods (tradables) in trade and service. Dynamic impacts on the full economy from the changes of transportation cost in any particular year can be evaluated.

Implementation

Equilibrium models can be implemented in numerous software packages. The models can be implemented in advanced programming software such as C++ and Visual Basic. It can also be developed in specific equilibrium modeling software such as GEMPACK and GAMS.

General Equilibrium Modeling PACKage (GEMPACK) is a suite of economic modeling software developed by Mark Horridge from Monash University, Australia. The package can be used for a wide range of economic behavior under general equilibrium and contains capabilities for solving complicated models such as recursive-dynamic and fully intertemporal models. Based on the GEMPACK platform, the GTAP group designed a standard multiregional and multisector CGE model that specifically caters to the GTAP database called RunGTAP. The model allows researchers to conduct country-level equilibrium simulations directly using the GTAP database without having knowledge in CGE programming. The latest version of GEMPACK is 11.1 released in 2012.

The next professional software for equilibrium modeling is General Algebraic Modeling System (GAMS). Originally developed at the World Bank,

GAMS provides solution algorithms for simultaneous linear and nonlinear equations. It consists of a language compiler and a stable of integrated high-performance solvers. The software allows for complex, large-scale equilibrium modeling applications and enables modelers to build large maintainable models that can be adapted quickly to new situations. Besides the basic GAMS platform, many specific solvers with advanced algorithms are developed separately that can be used for more complicated equilibrium modeling. Since GAMS allows executing codes including up to 300 variables without a commercial license, any student and researcher can download the trial version at <http://www.gams.com> and use it for free.

Limitation of CGE

Despite its rigorous capacity to measure policy effects on the economy, CGE models have the following limitations that are insurmountable. First, simulation results of equilibrium models rely on an assumed economic environment; in other words, the model is nonconditional. This means that although the purpose of general equilibrium modeling aims to model the real economy, it can never complete the goal due to the dynamic and complicated nature of real economic environments and relationships.

Second, the rationale of equilibrium modeling is to compare a simulated outcome from shocks of policy variables with the base outcome without any policy variation. Results of equilibrium modeling sometimes may be deceptive and sensitive given the fact that various determinants such as exogenous parameters, structures of equations, and values in SAMs may have influences on the simulation outcomes. Improving the reliability of parameter estimations for equilibrium modeling is important, but more importantly, the results of equilibrium models should be treated with caution and further applications or generalization must also be used cautiously.

E-Shopping

E-shopping, or online shopping, is the act of purchasing products or services over the Internet. The Internet has had, and continues to have, a profound impact on transportation systems and planning for future transportation networks as more and more

business-to-business (B2B), business-to-consumer (B2C), and consumer-to-consumer (C2C) transactions are conducted through e-commerce.

E-commerce can be defined as doing business over the Internet and refers to transactions that take place between organizations and people in societies. This method of shopping has been in existence for over a decade and, with the ever-expanding penetration of the Internet around the globe, it is unsurprising that e-shopping is increasingly popular among consumers and retailers around the world. With the advent of information and communication technologies (ICT) and online shopping have come new types of activity and travel patterns.

At present there are over 2 billion Internet users worldwide, and this number is predicted to rise to 3 billion by 2015. Global B2C e-commerce industry generated somewhere between \$400 billion and \$600 billion in 2010. According to 2013 figures from the eMarketer, North America currently has the largest market for B2C ecommerce. However, the BRIC countries' (Brazil, Russia, India, and China) share of online sales is growing rapidly, with forecasts suggesting that by 2015 Asia-Pacific will surpass North America in terms of B2C e-commerce spending. This rapid growth reflects the rise of Internet access in these major developing economies of the world.

In particular, China, with its burgeoning middle class with disposable income and a government-led campaign promoting consumerism, is set to rival the United States in terms of e-commerce spending. This growth in online shopping reflects the fact that China has the highest number of people purchasing goods online in the world.

Motivations

There is a general shift in spending from physical stores to online shopping. The motivations for changes in shopping behavior are complex and consequently difficult to address for future transportation planning. In general, e-shopping is often associated with the heightened convenience offered by shopping online. This is captured in terms of (1) the all-day everyday ability to purchase goods and services; (2) a perceived efficiency, reducing shopping time and stress; and (3) the absence of travel cost and time. Other benefits include a much wider choice that is not limited to geographic proximity to the consumer. This allows for price and quality comparisons between e-retailers. For these reasons,

personal travel and commercial vehicle operations are changing. Accessibility is no longer constrained and is not driven by travel time, distance, or travel costs as e-commerce dispenses with these elements. T. Golob and A. Regan discuss the structural changes undertaken by the freight transportation industry in response to the rapid increase in e-commerce and online purchasing activity. This includes the size of shipments, where freight is moved to, and the time frames for freight movements.

Transportation Impact

Undoubtedly, e-shopping and its growing global-market retail share changes travel behaviors, choices, trip frequencies, and carbon footprint of items and services purchased online. However, to date, there appears to be little empirical evidence providing insight into the impacts of e-shopping on travel. Researchers Orit Rotem-Mindali and Ilan Salomon suggest that online shopping is likely to reduce transport activity as telecommunications substitute the traditional physical journey made to a store. However, C2C has become popular through Internet sites such as eBay and Gumtree. This type of e-shopping can have a perverse effect on travel behavior by increasing travel trips, distances, and transport emissions in order for buy and sell transactions to be completed.

Similar to Rotem-Mindali, researchers Amalia Polydoropoulou and Andrea Papola recognize that telecommunications technologies and the Internet are likely to impact the demand for physical transportation and offer improvements in the efficiency and safety of transport systems, leading to a better environment through reduced travel and pollution, and time and material savings. This reflects earlier work done by scholar S. Cairns in 1996, which determined that e-shopping is more efficient not only in terms of vehicle miles traveled but also in reducing carbon emissions and energy use when compared to delivery based on consumer travel.

Individuals' e-shopping behavior and the effect on transport demand was considered by Polydoropoulou and Papola. Their research found that substitution of in-store shopping trips with e-shopping was prominent for specific product categories (especially grocery products). Evidence from research carried out by Cairns in 2005 in the United Kingdom and elsewhere found that substituting

car trips for van trips in grocery and other household shopping has the potential to reduce vehicle kilometers by 70 percent or more. Home delivery services for UK domestic shopping is increasingly replacing personal car travel for shopping. Polydoropoulou and Papola also concluded that the number of trips for other than shopping and work trip purposes, such as leisure trips, was not influenced by e-shopping. Results also indicated that technological improvements, such as improved online security systems and delivery options, have played a significant part in the decrease in shopping and work travel trips and the consequent rise of ICT use and e-shopping.

E-shopping can fundamentally change travel behavior. In a localized study conducted by scholar Sendy Farag and others in 2007, which explored the use of e-shopping and its impacts on personal travel behavior in the Netherlands, it was found that people living in areas with relatively many shopping opportunities buy online as often as do people who live in areas with relatively few shopping opportunities. The critical finding of this research is that the influences and demographics of e-shoppers remain undetermined.

It appears difficult, if not impossible, to identify specific characteristics associated with those choosing to shop online, and therefore the transportation response required is likewise difficult to determine with any certainty. Author Patricia Mokhtarian considers in a 2004 article analyzing causes of shopping-related changes in transportation that travel may reduce in some circumstances but in others travel may increase. Her conclusion is that there is no support that e-shopping will reduce net travel. She suggests that in the future there will be continued adoption of both store and e-shopping and that this presents formidable measurement challenges for assessing the transportation impacts of e-shopping.

It is clear that e-shopping is changing the way people conduct their lives and the way they do business. Over 2 billion people now buy groceries, electronic and electrical gadgets, clothes, travel tickets, and countless other products and services online. In some cases these purchases may be conducted in a completely virtual environment, for example, plane tickets; others may involve travel to collect an item and others will involve the delivery of that item to the online purchaser (whether that is B2C or B2B).

These all have varying impacts on transportation. The first takes items out of commercial haulage and delivery services, the second may increase personal travel both at a local level and farther afield, and the latter places demands upon the freight and haulage industries to adapt to different volumes and haulage loads, creating different haulage networks and routes.

While e-shopping is viewed as a means of reducing the number of personal travel trips and thus a corresponding improvement in road safety, it should be noted that the subsequent increase in deliveries by truck increases traffic in areas, often residential, which poses threats to pedestrian safety. For these reasons, it is clear that planning to meet future transportation needs is complicated by the inability to predict with any degree of accuracy the effects of e-commerce on travel needs.

Ethanol

Ethanol, empirical C_2H_6O and molecular CH_3CH_2OH (also known as ethyl alcohol, grain alcohol, drinking alcohol, and pure alcohol) is a volatile liquid suitable for use as a fuel. It has been used throughout history as a psychoactive drug in alcoholic beverages, fuel for lamps and heaters, an accelerant for fires, an ingredient in medicine, a component of synthesizing chemical products, and a transportation fuel. The largest use at present is as a transportation biofuel additive to gasoline for automobile engines. Ethanol can help reduce dependence on petroleum, increase octane, and reduce tailpipe pollution (including greenhouse gases from direct combustion).

Ethanol has a long history as a fuel. In 1826, U.S. inventor Samuel Morey developed an internal combustion engine that would run on ethanol and turpentine, and in 1860 German inventor Nicholas Otto fueled one of his engines with ethanol. By the 1890s, ethanol was used to fuel farm machinery in Europe. In 1896, Henry Ford built the Quadra-cycle, his first automobile, to run on pure ethanol. In 1908, he began production of the Model T. It had a flexible hybrid engine able to use gasoline, kerosene, or ethanol. Ethanol can also be used as a rocket fuel.

Ethanol can be produced directly from sugars through fermentation and distillation processes; from starches, as in maize or other grains, which must first be converted to simple sugars through a process called saccharification; from cellulose (wood, grasses, or the inedible parts of plants), which requires a greater amount of processing to produce the sugars needed for fermentation; and from ethylene, a petroleum by-product, by cracking a long chain of hydrocarbons found in crude oil at high temperatures and using a phosphoric acid or another appropriate catalyst. Bio and Petro ethanol have identical chemical formulas. Ethanol produced for fuel is usually dehydrated to increase its usable energy content per unit volume and/or to increase its ability to be mixed with gasoline or used directly as a fuel, and to reduce the risk of hydrous ethanol corrosion in vehicles. Dehydration is typically done through a single- or multistep distillation process with an additive such as benzene or by forcing the vapor through a molecular sieve.

Ethanol can be mixed with gasoline to increase the octane of the gasoline or used directly as a

fuel. It is used in standard mixtures ranging from 10 percent ethanol and 90 percent gasoline (E10) through E100 (100 percent ethanol). Engines must be designed specifically to use the ethanol mixture. Some vehicles (FFVs) use flexible fuel (flex fuel) engines, which are designed to use a range of different mixtures. Most modern (as of 2013) FFVs are optimized to use E15 to E85 fuels, though the technology exists to make engines that run on E0 to E100 and some vehicles are designed to do so.

Policies have played an important role in the use of ethanol. In the United States the unfavorable tax on camphene, a blend of kerosene and ethanol, in the late 19th century and the discovery of inexpensive oil combined to differentially encourage gasoline use in transportation. Prohibition in the United States (1920–33), which significantly reduced production of ethanol, also discouraged the use of ethanol as a fuel. The oil embargo in 1973 led to increased interest in renewable resources, including ethanol. However, it was not until the Energy Policy Act of 2005 and the Energy Independence and Security Act of 2007 that ethanol production significantly accelerated in the United States, the largest consumer of transportation-related petroleum products.

Brazil, the world's second-largest producer of ethanol after the United States, is also the world's largest exporter. Brazil has considered ethanol to be an important part of its fuel sources. With the oil crisis of the mid-1970s, Brazil, wishing to ensure energy independence, instituted the Programa Nacional do Alcool (National Alcohol Program) in 1975. This provided government funding to phase out dependence on petroleum in favor of ethanol produced from sugarcane, a major national crop since 1532. Production of ethanol from sugarcane is significantly more efficient than from maize, the primary feedstock in the United States. This is primarily because sugarcane has a high sugar content and does not rely on conversion from starch to sugar.

Bioethanol is subject to vagaries in the marketplace, just as any other commodity. Poor growing seasons can cut into the availability of feedstocks, as did the decline in sugarcane production from 2009 to 2012 in Brazil. Reduced supplies and increased prices for sugar reduced the sugarcane available for ethanol feedstock and affected bioethanol availability.

Most of the energy content of plants is in the cellulose, rather than the sugars and starch. Cellulosic ethanol can be produced from the cellulose by-products of agriculture, wood chips, cheat grass, other biomass, and waste. Production of cellulosic ethanol is generally less efficient (greater energy input than energy output). However, research funded by the United States, Brazil, other countries and private industry is improving the situation. For instance, DuPont built a successful test plant in Tennessee and planned construction of an operational facility in Iowa to open in 2014. Planning is under way for several cellulosic ethanol production plants with private and government funding by others as well.

Accounting for all energy inputs (all energy to produce the feedstock, transport it, and convert it to ethanol), grain-based ethanol has a slightly better energy output than input, and sugarcane-based ethanol has a significantly greater energy output than input. If successful, the cellulosic ethanol plants will significantly increase the ethanol output from maize, sugarcane, and other feedstocks.

From a grain grower's perspective, ethanol is a viable alternative to growing grain for food because a lower quality grain can be used and less care is required for storage and transport to the ethanol production facility than for food-quality grain.

While the use of grain for ethanol has affected the availability of grain for food, there are numerous other factors that have contributed to reduced availability of grain for food and driven food prices higher during the period from 2006 through 2012. These include, on the demand side, population growth, increased demand for meat, dollar devaluation, large foreign exchange reserves, aggressive purchases by importers, importer policies, and others. On the supply side, contributing factors include slowing growth in agricultural production, rising production costs, adverse weather, and exporter policies. While ethanol from food grains is an important contributor to food price increases, it is not the only one.

There are other issues related to bioethanol. To meet growing demands for energy with bioethanol, feedstock growth will need to expand, in large part by increasing acreage dedicated to feedstock. Converting forests of any type, peatlands, savannahs, grasslands, and some crop lands to the production of biofuels will create a carbon debt by pulsing 17 to

A microbiologist with the U.S. Department of Agriculture's Agricultural Research Service performs corn-to-ethanol research with a recirculating batch jet cooker, which models the liquefaction step in the dry-milling ethanol process.

420 times the carbon dioxide into the atmosphere than the annual tailpipe reduction from use of biofuels. Those increasing greenhouse gas concentrations will take many decades to draw down.

Conclusion

Research and development of cellulosic ethanol and alternative feedstocks are likely to improve the total energy output, reduce the demand for land conversion, reduce the demand for grain for fuel, and improve the ratio of greenhouse gas emissions per unit of energy produced. However, increased use of crop residue will change their availability to be returned to the soil and may increase the need for fertilizers to maintain soil nutrients and thus increase nutrient runoff from farmlands. Bioethanol is a valuable contribution to the fuel mix. However, the ramifications of expanding its use must

be considered to ensure that negative unintended consequences are limited or eliminated.

Ethical Issues

Ethics is a discipline dealing with the set of rules, principles, and beliefs used to judge the value of human actions. Ethics are relevant in the transportation sector because of the diversity and the social relevance of its effects, both positive and negative. Normative assessments of transportation plans and policies invoked by policy makers, researchers, and activists often use concepts such as equality, equity, fairness, and justice, which are informed by ethical views. Despite the increased interest in these issues in policy debates and research, there are few examples of actual attempts to explicitly address them in transport planning.

This article presents contemporary perspectives around ethical questions in transportation,

including social understandings of accessibility, risk, and environmental effects, as well as a review of transportation project evaluation methods and the implications of ethics for policy makers, researchers, and individuals and companies making decisions in the transportation market.

Transportation's Positive Effects

The purpose of transportation is to move people or objects from one place to another. Although in theory transportation systems enhance people's physical mobility, the design of the infrastructure may fail to address the specific needs of individuals who already face limitations to their physical mobility, such as the elderly and disabled people. If one accepts the propositions that all individuals have a right to mobility and that the individuals more vulnerable to losses of mobility should be given special attention, then society has the moral responsibility to meet the needs of these individuals.

Addressing these needs presupposes the implementation of proactive strategies to remove the barriers individuals face in accessing the transportation network, such as the introduction of buses without steps or the redesign of the street network to meet the limitations of elderly or disabled pedestrians. It can also involve measures of positive discrimination at the level of spatial planning, such as the attachment of priority status to the provision of public transportation in areas with high proportions of elderly people.

A broader view would also consider factors that prevent individuals from fully realizing the mobility potential offered by the transportation system. For economic reasons, young people and low-income or unemployed individuals may have limited access to private vehicles and are more vulnerable to increases in the costs of public transportation. Social and cultural aspects add to these factors to place other groups, such as women and ethnic minorities, at a potential disadvantage in the use of the transportation system.

The disadvantage of some groups may also have a geographic dimension, if they face limitations in the access of specific destinations such as jobs, schools, and facilities such as hospitals, parks, or food shops. Research shows that the processes of suburbanization and decentralization of jobs in many cities in North America and Australia and in some European cities have in many cases created

a “spatial mismatch” between the places and residences and work of low-income groups and racial minorities. The problem is compounded by lack of access to private vehicles and, in some cases, by the relatively low levels of provision of public transport in the areas where these groups are more concentrated. In most industrialized countries, the concentration of jobs and facilities in medium-sized towns and the closure of facilities in smaller towns and villages have also led to accessibility problems in rural areas, contributing to the isolation of the population in these places.

Disadvantages in accessibility levels depend not only on public policies in the transportation and other sectors but also on the decisions of individuals and companies (including transportation providers) in the free market. However, the problem is socially and politically relevant because unfulfilled mobility may contribute to the social exclusion of some individuals. This is because transportation fails to allow individuals to participate in activities and to access goods, services, and opportunities, with potential effects on their income, education and employment prospects, health condition, levels of social interaction, and overall life satisfaction. Once one considers exclusion as a social problem, then a need arises to consider the role of transportation in solving it. Policy makers and researchers have given more attention to the relationship between transportation and social inclusion in recent years and emphasized the relevance of providing transportation and removing barriers that limit the use of the system by some groups.

The recognition of society’s moral responsibility to ensure the inclusion of all individuals can be justified with the fact that social exclusion is linked to wider problems, such as unemployment and social unrest. The problem can also be understood in terms of concepts of equity or social justice. For example, John Rawls’s theory of justice emphasizes the need for society to provide all individuals with a minimum level of a set of “primary” or essential goods, in which one can include mobility and accessibility.

The concept can also be covered by Amartya Sen’s theory of justice, which focuses on individual capabilities to use primary goods to derive welfare. In the cases where a specific group is systematically at disadvantage in many regions, across time, or as a result of several projects, the issue can also be

framed in terms of the value of nondiscrimination. In fact, in the United States, activists and grassroots movements often use the term *transportation racism* to draw attention to the failure of the transportation system to meet the needs of racial minorities.

Social differences in mobility and accessibility levels can also be understood as “goods” that are distributed by society, distribution that is partly determined by policy makers. Theories of distributive justice or equity that are often used in economics can be applied to judge the distributive outcomes of the transportation system. Although these theories tend to include a concept of equality, they are better described as justifications for departing from equality. A usual distinction is that between horizontal and vertical equity. In the case of transportation, the application of principles of horizontal equity compares the distribution of mobility and accessibility across individuals judged to be comparable, while the application of principles of vertical equity would give higher priority to the individuals judged to be at a disadvantage.

Transportation’s Negative Effects

The outcomes of planning and policies in the transportation system can also be judged in terms of the level and the distribution of their negative effects. An important effect regards the negative environmental effects on the neighborhoods crossed by transport infrastructure, especially in the sections with high traffic levels, which are associated with high levels of air pollution and noise. The exposure to these impacts poses significant health risks for the population exposed.

The issue is often discussed using the concept of environmental justice. One interpretation of this concept is that there is a universal right to a clean local environment. In fact, like mobility and accessibility, environmental quality can be assigned the “primary” good status proposed in Rawls’s theory of justice. A possible way to translate this principle into transportation policies is to focus on “socially unacceptable” levels of transport pollution and noise. Justice would then be achieved through the definition of regulations or through the allocation of resources that ensure that those levels are maintained.

Examples are zone standards for pollution concentrations in each area or emission standards for vehicles. The definition of these standards is

theoretically related to the effects of pollution on human health, but in practice, they vary across countries, showing that there are relevant contextual (often political) factors in their interpretation.

An alternative perspective on environmental justice is the identification of cases of unbalanced distribution of environmental effects. Research in a large number of cities in North America and Europe has shown that low-income and racial minority communities tend to be disproportionately exposed to these effects. Grassroots activists and environmental organizations often justify the relevance of these patterns with the principle that the social distribution of environmental quality should not be detrimental to groups that are already at disadvantage in terms of the distribution of other resources, usually income or political power. This concept has been given increased political attention and has crawled into legislation in some countries. For example, in the United States, Executive Order 12898 outlines the actions to address environmental effects of public policies on low-income groups and racial minorities. Despite these initiatives, the issue remains the subject of intensive discussion among politicians, researchers, and activists, especially regarding the question of whether rights and distributive justice should refer to individuals only or to groups of individuals defined by ethnic or socioeconomic attributes.

At a wider level, transport pollution can also undermine long-term environmental sustainability and have consequences on the welfare of future generations. Motorized transportation contributes to the emission of carbon dioxide (CO₂), which is linked to climate changes such as global warming. Most transportation modes also contribute to the depletion of nonrenewable resources such as fossil fuel, while the use of biofuels has costs of opportunity in terms of resources diverted from food production. As the negative environmental effects are shifted into the future, issues of intergenerational justice arise. An often-used principle to approach this kind of problems is that future generations are vulnerable to the actions of the current generation and so the latter are morally responsible for irreversible environmental effects affecting the former. However, this general principle leaves many open questions, such as how far into the future should one be concerned about and whether and how to consider uncertainty over future developments

that may revert current processes of environmental deterioration.

The problem becomes more complex if one considers that developed countries are currently responsible for a disproportionate proportion of greenhouse gas emissions while the most severe effects of global warming are likely to occur in developing countries, due to their geographic location in more vulnerable areas of the globe. Questions of international justice also arise in relation to current levels of pollution, as some pollutants are dispersed in the atmosphere and may cross state and country borders. Arguments of environmental justice made at the level of individuals can therefore apply when looking at countries and are often summoned in negotiations of international environmental agreements.

The transportation system also has impacts on nonhuman beings. Land and water transportation disrupts wildlife and destroys habitats, and the short-term effects of air pollution and the long-term effects of global warming also affect biodiversity. Whether these impacts are morally relevant depends on one's understanding of whether nonhuman beings have moral status and whether the assignment of this status can override considerations of human welfare.

Safety Issues

Ethical issues also come into play when addressing accident risks. Society usually imposes safety regulations concerning vehicles, passengers, and passengers' use of vehicles. These regulations address the well-being of society in general, through the minimization of the number and gravity of accidents. Some of the regulations, such as the use of seat belts, can, however, be regarded as paternalistic, as society imposes behavior to protect individuals from risks that are not shared with the rest of society, although even in this case, regulations can be justified in terms of the rationalization of emergency and public health resources.

In the context of population aging in most developed countries, another important issue is whether society should promote or restrict driving by individuals of advanced age. The resolution of this question needs to balance competing societal objectives. Elderly drivers have a higher probability than average of being involved in accidents and are more vulnerable in the case of accident. On the

other hand, the ability to drive is a crucial factor for independent mobility, life satisfaction, and overall well-being in this age group. The imposition of regulations on driving license renewal and the mandatory screening and assessment of older drivers are therefore controversial measures.

The ethical aspects of transportation safety become more relevant when accident risks are not evenly distributed across society. For example, children and the elderly tend to be more vulnerable to pedestrian accidents. The concept of “justice as care” can be applied to defend that society should give priority to the protection of individuals in these age groups. In addition, empirical research suggests that the spatial distribution of pedestrian risk is also uneven and that individuals in low-income or racial minority communities tend to be disproportionately exposed to risk, due to higher traffic levels in these communities or to higher exposure times. The moral assessment of this pattern shares the same problems as the assessment of the distribution of other positive and negative impacts of transportation, especially the question of whether the racial and socioeconomic characteristics of the victims are morally relevant or if society should focus solely on the minimization of overall risk.

Public Intervention

Governments in most countries have some type of intervention in the transportation sector. At a broad level, this intervention needs to consider a balance between different societal objectives, such as economic efficiency, social justice, and environmental sustainability. At the level of each policy, there are also trade-offs among the welfare of users and non-users of the system, among different types of users, and among different types of nonusers.

Competing ethical principles may apply in the resolution of these conflicts. These principles are not necessarily universal, as each society has different concerns at each moment in time. There are also different ways to frame the objective of social justice in public policies. For example, adopting consequential views, the achievement of justice relies on the judgment of policy outcomes, while applying procedural views of justice implies the fairness of the decision-making processes leading to the definition of policies.

Conflicts may arise in the allocation of investment in the transportation system in different regions. The

concept of territorial justice is often applied in these cases. This concept may be supported not only by economic arguments but also by the moral responsibility of governments to promote regional cohesion and correct for imbalances in variables such as economic or demographic vitality of each region, given the crucial role played by transportation investment in the determination of these variables.

Further ethical issues arise in decisions about the construction of new transportation infrastructure. The choice of investment on private versus public transportation or of motorized versus nonmotorized transportation depends not only on economic principles but also on the governments’ normative assessment on the relative merits of different types of mobility and on the priority that should be attached to the needs of different types of users. Conflicts may be resolved by promoting policies addressing multiple social objectives. For example, the provision of infrastructure for walking and cycling, such as urban trail systems, can address accessibility and environmental issues simultaneously. At the level of each project, other subjective questions are whether, how, and how much to compensate the individuals affected by the negative impacts, including expropriations and safety and environmental effects.

The policies to address accessibility problems affecting some groups or areas may also be questioned on moral grounds when they collide with other societal objectives. The provision of public transportation and transport subsidies has effects in terms of the use and distribution of public resources, depending on the way such programs are financed. The provision of bus services in areas with low demand may also clash with the objective of environmental sustainability, as buses running with few passengers are responsible for a relatively high level of pollutant emissions per passenger.

The issue is also relevant in the case of traffic policies. Measures such as road pricing and traffic restriction are often applied with the objective of reducing safety and environmental effects in the areas of concern. However, this is only achieved by limiting the mobility of car users. It can be argued that these limitations violate their right or freedom of movement. The methods used to implement certain policies such as road pricing may also be questioned regarding their intrusion on road users’ privacy. The rights of road users then clash with the rights of mobility and safety of pedestrians and

cyclists and with the rights of safety and environmental quality of the residents in the areas where traffic decreases following the application of policies. This dilemma is resolved in practice by the application of principles regulating the allocation of space among different users and the regulation of the circulation of some users in some areas.

Traffic policies also have efficiency and distributional dimensions, as they imply the use and redistribution of resources. Traffic restriction policies reduce accessibility of both individuals and freight transportation and cause congestion. In some contexts, the people at disadvantage in terms of mobility and accessibility may be disproportionately affected. Regulations on traffic speed also imply a trade-off between safety benefits and time losses. Economic methods such as taxes have further distributional implications, depending on the base on which the tax is applied (ownership or use of private vehicles, distance traveled, or level of emissions). The revenues of the system may or may not be applied to improvements of the transportation system.

Regardless of the philosophical standings used to judge the desirability of public interventions, one should consider that policy makers are not a neutral apparatus applying policies to achieve the maximum social good. Controversial policies, such as policies with important distributional effects, may not have sociopolitical feasibility. The identification of fairness in policy outcomes and decision-making processes are important factors determining people's acceptability of these policies, and the need for public participation is increasingly called upon, especially in projects that affect social exclusion. There are also questions regarding the legitimacy of applying paternalistic policies that go against society's preferences. This can be the case of anticar policies, which yield environmental benefits that may not be recognized or valued by people. It may also be the case of policies subsidizing public transportation, as they represent a choice made by public planners on the set of choices faced by individuals.

Finally, policies are designed and applied by politicians and may reflect the ideology of their political party or be influenced by influential individuals or groups, leading to biased decisions. Powerful lobbies such as car manufacturers may influence decisions on traffic restriction policies. Different levels of political mobilization among the groups sharing the benefits and costs of transportation projects

may also influence the type and characteristics of these projects. For example, road alignments and the location of railway stations may be determined by political support or protest faced by policy makers in the affected areas.

Project Assessment and Evaluation

The inclusion of explicit ethical principles in the assessment and evaluation of transportation projects is usually limited to the acknowledgment of distributional concerns. In the United States, the Transportation Equity Act for the 21st Century (TEA-21) recognizes distributional impacts as required factors to assess regional transportation plans. A range of developed countries, such as England and Japan, have also attempted to include these concerns in their national transportation evaluation frameworks. Nevertheless, little consensus exists on the integration of the necessarily abstract and subjective principles of equity into current methods of evaluation, which are based on rigorous economic principles and methods.

Cost-benefit analysis (CBA) is by far the most frequently used method to evaluate transportation projects. This method is built around the hypothesis that a project should maximize total welfare across society. At its most simple, the benefits and costs of a project or policy are given monetary values, summed, and then compared. If the aggregate benefits exceed aggregate costs, the project is identified as having social worth and, in theory, should be implemented. The rationale for this formula relies on the principle stated by economists Nicholas Kaldor and John Hicks, which states that an outcome (such as the set of effects of a transport project) is desirable if the people who are made better off are able to potentially compensate the people who are worse off and still be better off. In practice, the final decisions over the implementation of the project are political and the results of CBA are treated as an indicator of the economic efficiency of the project, which is balanced against other social objectives.

As many of the effects of transport projects and policies are intangible, the application of CBA in this field relies on a series of well-developed methods to derive their monetary values. These methods are based on economic theory and intend to capture people's preferences, measured as willingness to pay or accept marginal units of the physical units of the effects of the project (such as, for example, minutes

of travel time, percent probability of accident risk, or noise decibels). Preferences can be estimated by using surveys (stated preference methods) or by looking at the prices of goods and services related to the effects and assuming that they reveal people's preferences over these effects (for example, looking at differentials in rents or house prices to value differentials in noise levels).

Despite its widespread use, CBA suffers from several weaknesses, identified in a large number of academic studies. Part of the criticism of the method revolves around the absence of links with ethical concerns. The argument is that any evaluation method incorporates judgment values, which should be made explicit. The focus in CBA on welfare maximization and people's preference reduces the normative assessment of projects to the principle of utilitarianism developed in the 19th century by Jeremy Bentham and John Stuart Mill. Economists have more recently studied possibilities of addressing other principles of distributive justice within the framework provided by CBA, for example, by attaching weights to the effects of the project on different social groups, but the use of these methods in actual project evaluation is still limited.

The necessity of translating all effects in monetary value has also attracted a fair deal of criticism. The assignment of a value to the increase of health and environmental risks and to lives saved and lost (usually measured as "statistical lives") is a sensitive issue. In addition, willingness to pay depends not only on individual preferences but also on ability to pay and so the values assigned to the benefits and costs of a project are biased toward the preferences of individuals of higher income.

The reliance on the estimation of people's preferences may fail to address ethical concerns even when these preferences are not measured in monetary terms. Philosophers such as Jon Elster have drawn attention to the concept of "adaptive preferences," that is, preferences that are determined by context. This concept is relevant in the transportation field, as there is evidence that disadvantaged groups may not recognize their disadvantage in terms of mobility and accessibility or the degree to which they are exposed to transport pollution.

Issues of intergenerational equity are also not made explicit in CBA. Benefits and costs occurring in the future are usually discounted by calculating their net present value, but the definition of the

methods and parameters used in this procedure are far from being consensual.

In order to overcome the limitations of CBA methods to address equity concerns, alternative approaches have been developed, of which the most important is multi-criteria analysis (MCA). This method is based on the definition of a set of indicators in the assessment that are combined by a structured set of weights measuring society's preferences. The indicators are not necessarily measured in the same unit. This approach has the potential of including diverse ethical concerns in project assessment, although this may also be regarded as a weakness, given the subjectivity in the determination of weights.

The use of MCA has been growing in recent years, especially in the assessment of large-scale transport projects. The combination of CBA and MCA methods within the same evaluation framework has also produced encouraging results, such as in the case of the planning of the trans-European transport network (TEN-T).

At the level of measurement of benefits and costs, there is also growing academic research on methods that surpass the need for monetization and attempt to measure the "value of use" of effects such as mobility and accessibility. As with other approaches capturing ethical concerns, the main limitation to these methods is the high degree of subjectivity and perhaps paternalism in their application.

Ethics in Transportation Research

Ethical issues are also relevant at the level of research conducted by academics and consultants. An important aspect regards the independence and impartiality of the studies, as researchers may be influenced by the institutions commissioning projects or awarding funding. Codes of conduct are common in academic research and are especially important in the case of transportation research. Transportation projects are expensive infrastructures with large and far-reaching effects. The resolution of dilemmas over the redistribution of resources and welfare linked to these projects is informed by the results of research. Therefore, a degree of moral responsibility for the consequences of the project lies with researchers, who may face personal dilemmas over which methods to use and which results to report. The common good, the interests of the commissioners of the

research project, and the researchers' own ethical views may differ.

The role of ethics comes into play at the stages of both data collection and analysis. This may involve the decisions regarding the object of analysis, for example, individuals at risk of social exclusion tend to be underrepresented in surveys and interviews. Ethical presuppositions are also unavoidable in the choices of the scenarios studied and the variables used in the assessments of benefits and costs, as researchers may feel pressured to obtain and report optimistic results. This may lead to biased estimates for the project's demand or to a discrepancy between forecasts and actual costs. The selection of which external costs to include in the analysis and of the methods to measure the level and distribution of those costs are also subjective decisions. The models generally used in transportation research also have implicit assumptions, as they tend to be based on economic theory and rely on quantitative data, which may prevent the analysis of intangible costs and questions of social justice.

Ethical Aspects of Individual Behavior

While ethical considerations are relevant for policy makers and researchers judging the social worth of transport projects and policies, they may also inform the preferences and choices of individuals and companies making decisions in the transportation market.

Ethical motivations are especially relevant in decisions over modal choice, such as the use of public transit (versus private vehicle) and land transport (versus air transport). These decisions may be partially based on altruistic or environmental reasons. These reasons may also be applied in decisions over the type of vehicle owned (such as the choice of electric cars). Individuals may also choose to reduce the number of trips or the distance traveled (for example, in commuting to work). There is still little quantitative research, however, on the role of these types of motivations in people's willingness to pay for improvements in the social and environmental aspects of transportation policies.

On the supply side, the process of deregulation of the transportation sector in many countries raises questions regarding the social responsibilities of companies in the private transportation sector. Critics of these processes often point to the fact that private companies cannot attend to these issues to

the same degree that organizations in the public sector do, as this can compromise their commercial viability. The survival of these companies may be incompatible with some of society's objectives. For example, the level of the fares that maximizes economic efficiency may exclude some users from the system. Private operators also do not have the incentive to serve areas with small demand, such as rural areas, dispersed suburban areas, and areas with high rates of car ownership, while car manufacturers do not have the incentive to reduce the environmental impact of their products. Employment issues are also relevant as women and racial minorities tend to be underrepresented in managerial positions and in certain professions in companies in the transportation sector.

Some sectors in the industry face particularly complex ethical challenges. Aviation is one of the human activities with a higher share of responsibility for the emission of greenhouse gases and has a substantial impact on the local environment in areas around airports. As such, the consequences of the growth of aviation companies, including the increase in air traffic and the construction or expansion of airports, are always subject to much public discussion. Safety is also a crucial aspect in air transportation, and public authorities and companies in the industry usually impose strict regulations and codes of conduct to minimize risk.

Companies in the freight transportation industry also face specific moral issues. The globalization of channels of production and distribution of goods has increased the environmental impact of the transportation of goods, contributing to the depletion of natural resources and climate change. There is no consensus on whether freight transport companies are morally responsible for these effects, as they depend on national and international regulations and, ultimately, on the demand for and supply of the products carried. The transportation of some goods, such as hazardous materials, also involves public health risks. Decisions involving the routes taken in their transport are politically sensitive, and activists have often claimed that these routes tend to cross low-income and ethnic communities.

ameliorating these problems is the principal concern of evacuation planning. The resulting evacuation plan describes aspects and contingencies in the evacuation process under the broad goal of moving people out of the threat area in the least amount of time and with the least amount of risk.

Evacuation is generally divided into six overlapping time phases: incident detection time, decision time, notification time, preparation time, travel time, and verification time. Incident detection time is the time it takes officials to detect that an event has occurred. In the case of a hurricane, this might be done via satellite days prior to landfall, but the challenge of detecting the release of an odorless, invisible toxic gas from a storage site would be much greater. Decision time is the time it takes officials to determine whether to recommend protective actions to the public. Notification time is the time it takes to communicate a warning message to the public through radio, television, the Internet, or other media. Preparation time is the time it takes the public to gather family members, pets, and valuables prior to departing. Travel time is the time it takes evacuees to move from an origin in the threat area to a safer destination. Verification time is the time it takes officials to determine whether everyone has left the threat area.

Each of these time phases can alternatively be viewed as a series of questions for evacuation planning purposes. The principal question in the incident detection phase is this: how will an event be detected and monitored in a timely manner? The answer to this question might be by remote (hurricane) or in situ sensors (tsunami), whereas in the case of a wildfire or sudden hazardous material (hazmat) highway spill, the plan might be to rely on eyewitnesses with cell phones. Three important questions that need to be answered in the decision-time phase include who needs to take action, what is the best action, and when do they need to take it?

The answers to these questions comprise the basics for an official warning message. The primary planning question in the preparation phase is how can one best prepare the public such that their response to a future evacuation recommendation is likely and timely? The travel-time phase is where the most significant transportation questions arise, including what are the likely origin-destination flows, travel modes, routing, and roadway control? The question in the verification phase is how will officials

Evacuation Planning

Events ranging from hurricanes to hazardous material spills represent environmental threats to people and property. Evacuation is the process of moving at-risk populations to safety by relocating them outside a defined threat area. As evacuation is primarily about human movement, it has substantial behavioral and transportation dimensions. Evacuation planning is the process of anticipating how to best move people to safety should a disaster occur. There are many problems that can arise in an evacuation that serve to delay or prevent officials from evacuating everyone quickly, and anticipating and

A hurricane evacuation route leads drivers to safety in Corpus Christi, Texas, three days before Hurricane Ike makes landfall, September 10, 2008. Some people failed to heed evacuation warnings, which contributed to the 84 deaths caused by Ike.

determine who has evacuated, who has not, and what should the at-risk population that is not clear of the threat area do (for example, shelter-in-refuge)?

The principal behavioral goals in evacuation planning are (1) to communicate the warning message to the most at-risk people possible and (2) to achieve the highest compliance level—the percentage of people who adopt the recommended action. The most powerful behavioral tool in an emergency manager's toolkit is a well-crafted warning message that includes unambiguous instructions regarding who needs to take action, what action they should take, and why they should take it.

Furthermore, a wealth of research has repeatedly shown that warning people is a social process, that is, people need to confirm the warning with family, friends, and coworkers. In the best case, the at-risk population will be able to easily combine environmental cues (for example, smoke, flame, wind) with a well-crafted warning message received from multiple sources and subsequently confirm this with family and friends to make the decision to evacuate in a timely manner.

The concern on the transportation side of evacuation planning is moving the people that wish to evacuate to safety in the least amount of time (that is, minimizing the travel-time phase). This can involve many facets, including routing instructions, departure time staging, contraflow operations, intersection control, and public transport. Evacuation routing can be done at a variety of scales from recommending major highways as primary exits or as fine as the traffic lane-level in urban evacuations (that is, recommending the precise lanes that each neighborhood in the evacuation zone should use).

Departure staging is the process of reducing traffic congestion by subdividing the threat area into smaller, manageable areas, each of which is then assigned a particular time window within which to depart. Contraflow operations refer to the process of reversing roads or lanes to increase the road capacity away from the threat area. Critical intersections can also be reconfigured to take advantage of the fact that vehicle flows have directionality in an evacuation (that is, away from the threat area). In cases where private vehicle ownership is low, public transport options may aid in moving people out of the threat area.

As large-scale evacuation drills are generally infeasible in evacuation planning, analysts rely on computational models to run “what if?” scenarios. This process involves gathering geographic data on the anticipated threat area surroundings, including the whereabouts and attributes of the population, roads, and potential shelters. Relevant attributes of the population include demographics, vehicle ownership, and socioeconomic level. Important roadway attributes might include the number of lanes, directionality, and vehicle capacity. Potential shelter locations and associated capacity can also be helpful information.

Evacuation models generally have a behavioral component that allows an analyst to vary the assumptions regarding who will respond to a warning message, how soon they will evacuate, how many vehicles they will utilize, and what routes they will likely take. A second model component represents the traffic flow process with the goal of testing how well the surrounding road network may perform under the added stress of evacuation travel demand (that is, over normal traffic flow patterns).

The results of this exercise provide a realistic range of evacuation-time estimates (ETEs) for a threat area, along with potential traffic bottlenecks and the most effective strategies for assuaging these bottlenecks (for example, departure staging, contraflow operations, intersection control).

Evacuation planning is a very vibrant research and practice area, and current topics include the role of social media in evacuation decision making, using locationally aware devices to provide precise protective-action recommendations to threatened subpopulations (that is, geotargeting), designing geosensors to detect likely threat events, providing public transport options for carless populations, and designating in-place shelter options that can avoid the need to evacuate.

Finally, regardless of how effective evacuation planning, modeling, and associated exercises can be, many evacuation decisions in actual disaster events are improvised on-the-fly. Nonetheless, it is very worthwhile to discuss likely threat events and the associated evacuation procedures that might take place, as well as to formalize the outcome of this process in an evacuation (or protective) plan.

Executive Order 12898

Executive Order 12898 is a federal policy intended to address threats to environmental justice in the United States. According to the U.S. Environmental Protection Agency (EPA), environmental justice is "the fair treatment and meaningful involvement of all people regardless of race, color, sex, national origin, or income with respect to the development, implementation, and enforcement of environmental laws, regulations, and policies." Transportation agencies must integrate Executive Order 12898 into local planning practices in two primary ways: (1) assessing and addressing potential environmental justice impacts of transportation projects and (2) conducting public involvement in a way that considers environmental justice. The EPA and the U.S. Department of Transportation (USDOT) offer much technical guidance to this end, in that many complementary federal and local policies facilitate the implementation of Executive Order 12898.

Overview

In 1994, President William Clinton issued Executive Order 12898: Federal Actions to Address Environmental Justice in Minority Populations and Low-Income Populations. Executive Order 12898 draws attention to environmental and human health effects of federal actions on minority and low-income populations. It calls on federal agencies to make environmental justice part of their mission, assessing and addressing it under each major program, policy, and activity. Executive Order 12898 does not create a process for judicial review to measure compliance:

[It is] intended only to improve the internal management of the executive branch and is not intended to, nor does it create any right, benefit, or trust responsibility, substantive or procedural, enforceable at law or equity by a party against the United States, its agencies, its officers, or any person.

In 2011, President Barack Obama issued a Memorandum of Understanding (MOU) on Environmental Justice and Executive Order 12898. The MOU signified renewed attention to formalizing the commitment of federal agencies to environmental justice. It called upon major federal agencies

to each draft an environmental justice strategy, including goals for partnering with other federal agencies to address environmental justice issues. The MOU added areas of focus not explicitly outlined in its predecessor, Executive Order 12898, such as climate change adaptation and commercial transportation. Notably, the MOU highlighted the role of the National Environmental Policy Act and Title VI of the Civil Rights Act of 1964 as policies that concurrently seek environmental justice.

In recognition of the 20th anniversary of Executive Order 12898, as the nation's lead environmental agency, the EPA put forth Plan EJ 2014 in July 2010. As the EPA emphasized, Plan EJ 2014 is not a rule or regulation but a strategy for integrating Executive Order 12898 into the agency's daily activities through cross-agency focus areas, tool development, and program initiatives. Plan EJ 2014 attempts to strategize around five cross-agency focus areas: incorporating environmental justice into rulemaking, considering environmental justice in permitting, advancing environmental justice through compliance and enforcement, supporting community-based action programs on environmental justice, and fostering administration-wide action on environmental justice.

Two key groups have guided overall execution of Executive Order 12898 and the MOU on Environmental Justice and Executive Order 12898: the Federal Interagency Working Group (IWG) on Environmental Justice and the National Environmental Justice Advisory Council. The IWG met for many years in the early mid-1990s, and heads of 17 agencies and the White House offices signed on to the 2011 MOU to renew this group. The administrator of the EPA convenes the IWG, a group comprising representatives from the Departments of Agriculture, Commerce, Defense, Education, Energy, Health and Human Services, Homeland Security, Housing and Urban Development, Interior, Justice, Labor, State, Transportation, and Veteran's Affairs, as well as the General Services Administration, Small Business Administration, and the White House offices.

To codify their efforts, the MOU on Environmental Justice and Executive Order 12898 required that the IWG adopt a charter that outlines membership, meeting expectations, and coordination of committees, including three permanent standing committees: the Public Participation Committee, the Strategy and Implementation Progress Report

Committee, and the Title VI Civil Rights Act of 1964 Committee. Also, since 1993, the National Environmental Justice Advisory Council, a group of approximately 25 stakeholders representing academia, community groups, industry, tribal groups, nongovernment organizations, and local governments across the United States, has guided implementation of Executive Order 12898.

The U.S. Department of Transportation

To carry out Executive Order 12898, the USDOT issued an agency-wide Order to Address Environmental Justice in Minority Populations and Low-Income Populations (USDOT Environmental Justice Order) in 2012 (6640.23a), an updated replacement of the 1998 version of this order (6640.23). The 2012 USDOT Environmental Justice Order outlines the process that the office of the secretary and each operating administration must use to integrate the goals of Executive Order 12898 into existing programs, policies, and activities to make assessment of environmental justice common practice. Similar to Executive Order 12898, it states that disproportionately adverse environmental health impacts on minority or low-income populations should be avoided during transportation planning, unless such actions lead to substantial harmful impacts on other valued social, economic, or environmental resources. Also akin to Executive Order 12898, subsequent USDOT orders are not upheld by judicial review or law for compliance and act, rather, as guidance policy.

The USDOT Environmental Justice Order also explains how Executive Order 12898 should be reinforced through existing policies, including the National Environmental Policy Act (NEPA), Title VI of the Civil Rights Act of 1964 (Title VI), the Uniform Relocation Assistance and Real Property Acquisition Policies Act of 1970 (URA), major federal transportation bills, and other USDOT policies. For instance, the Council on Environmental Quality guides agencies and consultants conducting NEPA analyses on how to integrate environmental justice considerations into compulsory steps during the development of major, federally funded transportation infrastructure: scoping, environmental assessment, alternatives analysis, determination of mitigation strategies, public commenting, and decision making.

Further, Title VI states that federal agencies must ensure that no person is discriminated against on

the basis of race, color, or national origin, under any federally supported program (for example, Transportation Alternatives Program) or infrastructure development from site scoping to post-construction maintenance. Additionally, the URA ensures that displaced property owners, such as those in the footprint of a proposed transportation development, are treated “fairly, consistently, and equitably” in the process of property acquisition that may occur to prepare for a new or expanded highway, bridge, or public transit center.

Implementation

The USDOT undertakes a variety of strategies to implement Executive Order 12898 and the USDOT Environmental Justice Order across operating administrations (for example, Federal Aviation Administration or Federal Transit Administration) and through interagency efforts. The Federal Highway Administration, for instance, ensures that policy documents reflect Order 6640.23a, disseminates environmental justice guidance and research to assist transportation planners, conducts related trainings and Webinars across the country, and coordinates professional development to improve implementation of the USDOT Environmental Justice Order. The USDOT also engages in interagency efforts, including involvement in the EJ IWG’s various subcommittees and Partnership for Sustainable Communities, a collaboration between the USDOT, EPA, and Department of Housing and Urban Development.

Locally, implementation of these environmental justice policies requires the work of state transportation departments, metropolitan planning organizations, transit providers, other transportation providers, and the public. The USDOT highlights these local examples on its Web site, providing successful case studies of planning initiatives, right-of-way developments, environmental assessment procedures, and public involvement efforts that appropriately assess and address environmental justice.

The EPA and USDOT provide technical guidance to agencies and consultants doing this work. Yet, much variation remains across the nation in the implementation of the USDOT Environmental Justice Order, for instance, in selection of geographic scope and specific methods, as well as public involvement and decision-making processes.

Data collection and analysis is necessary to assess implementation of Executive Order 12898 and the USDOT Environmental Justice Order, often in the context of a specific freight or transit project. In communities hosting existing or proposed transportation infrastructure, transportation planners rely on a range of methods and frameworks to conduct these assessments, such as mapping analyses, field visits, business/housing replacement studies, community leader interviews, surveys, oral histories, and community impact assessments. This may entail close examination of secondary data, such as the U.S. Census Bureau’s American Community Survey or the Office of Highway Policy Information’s National Household Travel Survey, to study demographic, health, economic, and transportation patterns. For federally funded projects, these assessments are typically coupled with extensive environmental assessments mandated by NEPA, often including projections for air, noise, and water pollution. The USDOT Environmental Justice Order requires that the USDOT maintain information on the race, color, national origin, and income level of persons negatively affected by USDOT programs, policies, and activities.

Executive Order 12898 and the USDOT Environmental Justice Order also outline expectations regarding public involvement. Public involvement may address environmental justice issues by increasing opportunities for information sharing, public commenting or forums, and dialogue between residents, organizational leaders, and decision makers during transportation deliberations. The USDOT Environmental Justice Order specifically requires that public involvement procedures include members of minority and low-income populations who may be disproportionately burdened by a transportation project. Executive Order 12898 and the USDOT Environmental Justice Order also complement and reinforce a variety of federal policies that include guidance on public involvement. For instance, the Safe, Accountable, Flexible, Efficient Transportation Efficiency Act of 2005 specifically applied NEPA public involvement requirements to transportation planning.

NEPA now requires public comment periods during environmental assessment for federally funded transportation projects. In another example, Executive Order 13166 of 2001 orders that federally conducted programs and activities be accessible to persons with

limited English proficiency. To meet this mandate, transportation planners often print outreach materials and environmental assessment documents in Spanish or other locally appropriate languages.

Related Agency Definitions

Executive Order 12898 and the USDOT Environmental Justice Order use the following terms and definitions: Low-income means a person whose median household income is at or below the Department of Health and Human Services poverty guidelines. A minority is a person who fits any of the following criteria:

1. *Black*. A person having origins in any of the black racial groups of Africa.
2. *Hispanic or Latino*. A person of Mexican, Puerto Rican, Cuban, Central or South American, or other Spanish culture or origin, regardless of race.
3. *Asian American*. A person having origins in any of the original peoples of the Far East, southeast Asia, or the Indian subcontinent.
4. *American Indian and Alaskan Native*. A person having origins in any of the original people of North America, South America (including Central America), and who maintains cultural identification through tribal affiliation or community recognition.
5. *Native Hawai'ian and other Pacific Islander*. People having origins in any of the original peoples of Hawai'i, Guam, Samoa, or other Pacific Islands.

Adverse effects means the totality of significant individual or cumulative human health or environmental effects, including interrelated social and economic effects, which may include, but are not limited to, the following: bodily impairment, infirmity, illness or death; air, noise, and water pollution and soil contamination; destruction or disruption of human-made or natural resources; destruction or diminution of aesthetic values; destruction or disruption of community cohesion or a community's economic vitality; destruction or disruption of the availability of public and private facilities and services; vibration; adverse employment effects; displacement of persons, businesses, farms, or nonprofit organizations; increased traffic

congestion, isolation, exclusion or separation of minority or low-income individuals within a given community or from the broader community; and the denial of, reduction in, or significant delay in the receipt of, benefits of USDOT programs, policies, or activities.

Disproportionately high and adverse effect on minority and low-income populations means an adverse effect that (1) is predominately borne by a minority population and/or a low-income population, or (2) will be suffered by the minority population and/or low-income population and is appreciably more severe or greater in magnitude than the adverse effect that will be suffered by the nonminority population and/or non-low-income population.

Federal Aid Highway Program

The Federal Aid Highway Program (FAHP) traces its roots to the Federal Aid Road Act of 1916, which defined the federal-state cooperative approach that underpins the country's highway infrastructure. The Federal Aid Highway Act of 1956 cemented this relationship and launched the modern FAHP, which has been continued or renewed through the multiyear authorization acts. In addition, since 1978, Congress has passed highway legislation as part of more comprehensive, multiyear surface transportation acts. Starting with the 1962 Federal Aid Highway Act, the FAHP has evolved from a primary focus on building the interstate system to a more complex, multimodal program that today funds a variety of functions related to surface transportation as new programs and areas of concern have been added to the FAHP.

The FAHP is an umbrella term referring to activities administered by the Federal Highway Administration (FHWA) but in cooperation with and administered by the states and their localities. Several components make up the FAHP, comprising separately funded categories of activities such as the Interstate Maintenance Program, Surface Transportation Program, Bridge Program, and Congestion Mitigation and Air Quality Improvement Program. Noncapital costs include routine

maintenance (those activities required to keep the highway open for public travel), administration, law enforcement, and debt service.

Historically, the FAHP (and the associated federal-aid funding) has been focused on capital construction activities, most prominently the interstate construction program. While some funding could be used for resurfacing, rehabilitation, or restoration (3R), the emphasis was on new or major reconstruction efforts. With construction of the interstate system essentially complete, and recognition that resources at all levels of government are shrinking, the federal emphasis has shifted to include 3R, preventive maintenance, and management/operations efforts. However, most costs for nonconstruction or noncapital activities are still the responsibility of state and local governments.

The FAHP has three main characteristics: (1) funds are apportioned to the states according to a legislated formula with state transportation agencies having responsibility for implementation of FAHP projects, (2) the states are required to provide matching funds (the current federal share is 90 percent for interstate projects and 80 percent for noninterstate system road projects), and (3) federal funds can generally be spent only on designated federal-aid highways.

History and Evolution of Legislation

The Federal Aid Road Act of 1916 appropriated federal funds for the construction of rural post roads

and for roads and trails within national forests. It also established basic policy for the development of main roads serving federally owned lands, reservations, or areas. In addition, this legislation initiated the advance funding approach fundamental to the FAHP. Congress appropriated \$5 million for fiscal year 1917, with annual \$5 million increases up to a maximum of \$25 million by 1921. This long-term commitment and advance appropriation allowed the states to plan ahead and build a more structured and orderly highway program. This legislation also established the federal–state partnership approach to the FAHP by (1) making state participation permissible provided that the state complies with the legislation’s provisions, (2) clarifying that the authority and responsibility of initiating projects was reserved for the states and that federal participation was dependent upon approval by federal authority, and (3) stipulating that the state highway department or its equivalent would represent the state in its administration of the program.

The Federal Aid Highway Act of 1921 divided highways into two categories: primary (interstate) and secondary (intercounty). It also gave limited federal aid to a system of highways to be designated by each state, not to exceed 7 percent of the state’s total mileage. This legislation stated that each state would be responsible for maintaining the highways constructed with federal funds. Failure to meet this requirement would result in direct federal supervision of this work, using funds that would otherwise be available to that state for new construction.

The Federal Aid Highway Act of 1944 extended the FAHP by designating a National System of Interstate Highways. This legislation appropriated \$225 million for primary roads, \$150 million for secondary and feeder roads, and \$125 million for urban federal-aid highway construction, annually. More importantly, the legislation established apportionment formulas for federal funding to be received by each state. However, no funds were authorized or appropriated for the interstate highway system. The Federal Aid Highway Act of 1952 was the first legislation to provide funds specifically for interstate highway construction, authorizing \$25 million for the interstate system on a 50 percent federal–50 percent state matching (50–50) basis.

The Federal Aid Highway Act of 1956 dramatically increased federal aid for highways. This legislation established the current Interstate Highway System

and created the Highway Trust Fund (HTF) as the mechanism to finance it. Funding for interstate projects was on a 90–10 federal–state basis, compared to the 50–50 match that previously existed (and remained for all other noninterstate projects).

Postwar Era

The postwar era witnessed steady growth in the size and number of suburbs around major cities, as people moved outward from urban hubs and automobile use grew apace. The 1962 Federal Aid Highway Act responded to the multiple effects of suburbanization by mandating urban transportation planning that was continuing, comprehensive, and cooperative (3C planning). Thus, in order to gain approval of a federal-aid highway project, states and localities, working together, had to construct an area-wide, comprehensive plan. The act stipulated that these plans were required to consider impacts on mass transit and land use along with the locations for new highway facilities. The act also addressed the need to assist those displaced by highway construction.

The subsequent Federal Aid Highway Act of 1968 expanded the Interstate Highway System by 1,500 miles and applied the Davis-Bacon Act to federally funded highway construction projects. The latter increased the cost of highway projects by mandating that public works projects pay the prevailing wage in a given locality. The 1966 act also increased flexibility in the use of interstate funds by allowing fund transfers from nonessential interstate routes to other interstate routes. Finally, the act incorporated several provisions to protect the environment by reducing some of the negative effects of highway construction. For instance, it applied the requirements of Section 4(f) of the Department of Transportation Act of 1966 to highway projects. Section 4(f) protects publicly owned parks or land designated or administered as a public park. It also protects publicly owned recreation areas and wildlife and waterfowl refuges. In regard to historic properties, it protects both privately and publicly owned properties either on or eligible for the National Register of Historic Places.

1970s and Beyond

The Federal Aid Highway Act of 1970 increased the federal share for noninterstate projects from 50–50 to 70–30 and created the Special Bridge Replacement

Program (SBRP) under the FAHP umbrella with a federal share of up to 75 percent. This legislation also created a minimum apportionment guarantee for each state for its respective highway funding.

Subsequent legislation diverged from a primary focus on funding for highways toward a much more multifaceted role for the federal government in transportation and highway policy. The Federal Aid Highway Act of 1973 authorized funds to complete the Interstate Highway System, officially named the National System of Interstate and Defense Highways. Reflecting a turn to multimodal transportation policy, this legislation also funded construction of bus lanes and highway traffic control devices and included, for the first time, provisions allowing use of federal funds for the construction of bicycle lanes, bicycle facilities, pedestrian walkways, and fixed-rail transit facilities.

The 1976 Federal Aid Highway Act established the 3R program, which, for the first time, allowed federal funds to be used for resurfacing, restoration, and rehabilitation of existing highways with a 90–10 match for interstates and a 75–25 match for other roads and highways. The Surface Transportation Assistance Act of 1982 provided for major increases in funding for bridge replacement and rehabilitation. This legislation also addressed the donor–recipient debate that existed with regard to the FAHP by creating an equity adjustment mechanism that assured each state would receive no less than 85 percent of its fuel tax and other contributions to the HTF.

By the late 1980s, the interstate system was largely completed. The Intermodal Surface Transportation and Equity Act (ISTEA) of 1991, the first postinterstate legislation, designated the National Highway System (NHS) as the only federal-aid highway system. The NHS included the interstate system and other routes that carry a large portion of the nation's highway travel. It also includes facilities that serve strategic priorities and that connect to major military installations, border crossings, airports, ports, and rail-highway transfer.

ISTEA also established the Surface Transportation Program within the FAHP, which allowed spending on projects that had previously been considered below the federal level of responsibility. These included construction, reconstruction, rehabilitation, and operational improvements for highway and bridges, bike transportation, pedestrian

walkways, and transportation enhancements to the federal-aid system. The 1998 Transportation Equity Act for the 21st Century (TEA-21) enacted a minimum guarantee for state funding of at least 90.5 percent of each state's contribution to the HTF. The Safe, Accountable, Flexible, Efficient, Transportation Equity Act: A Legacy for Users (SAFETEA-LU) Act of 2005 extended the FAHP authorization while broadening the states' ability to toll interstate highways and to operate high occupancy lanes on federally funded highways. Under the 2012 Moving Ahead for Progress in the 21st Century (MAP-21) Act, 92 percent of FAHP funding is distributed on a formula basis (through five core programs) whereby each state's share is based on a calculation set out in the law. The remaining funds, distributed through discretionary programs, are administered more directly by FHWA but with some formulaic determinations.

Structure and Funding

The FAHP is jointly administered and funded by the federal and state governments. With few exceptions, FHWA does not provide full funding for any FAHP project. Each funding category has an established funding ratio that defines the federal share of the project cost. The remaining funding comes from the state or localities. The federal–state partnership is the basic element of the FAHP. To be eligible for federal-aid funding, a state must have a state transportation agency capable of fulfilling the duties and requirements established by federal legislation. The FHWA provides funding, guidance, and technical assistance to the state transportation agency, and localities may receive federal funding through their respective states. However, the state remains responsible for ensuring all federal requirements are met for these local projects.

The FAHP does not require the passage of an appropriations bill before projects can be approved. The FHWA, through periodic authorization legislation, receives contract authority over monies in the HTF, which allows obligation of funds in advance of appropriations. The use of contract authority gives the states advance notice of the size of the FAHP (and associated funding) at the time an authorization act is enacted and eliminates the uncertainty contained in the authorization-appropriation sequence.

The FAHP is a reimbursable program, not a “cash up-front” program. When authorized amounts are

distributed to the states, no cash is actually disbursed. Instead, states are notified that federal funds are available for their use and that they can incur financial obligations, begin projects, and receive reimbursements for costs incurred. Depending on the type of project, the time elapsing from obligation to reimbursement can vary from a few days to several years.

provisions established long-lasting precedents that were reenacted time and again as central features of subsequent federal transportation acts over the next century.

There was no systematic federal or state involvement in road building in the United States until the closing years of the 19th century. Up until then, the only nonlocal road-building efforts were privately operated turnpikes financed by tolls—all of which had long since gone bankrupt and been turned over to local governments and allowed to disintegrate. Starting in the 1890s, however, intercity roads were gradually recast as a public endeavor, managed by newly created government bureaucracies. Furthermore, drivers were no longer expected to pay for the costs of the newly constructed roads. This reconception of roads and highways, from commodity to free-of-charge public good, was ultimately institutionalized by the passage of the Federal Aid Road Act of 1916.

The Good Roads movement was started by bicyclists in the 1880s and gained momentum when a leading bicycle manufacturer, Albert Pope, decided to pay the expenses of the League of American Wheelmen. He not only wanted to spread the word about the benefits of his product, he also wanted to harness the mass-politics power of bicycle owners to push for more and better roads, which would in turn make his product more practically usable. This business development strategy, started in the bicycle industry, was subsequently adopted by the nascent automobile industry. By the turn of the century, the newly formed Automobile Association of America (AAA), with the financial backing of automobile manufacturers, replaced the wheelmen as the driving force behind the movement.

Organizations that represented rural Americans also favored public funding of roads, arguing that their constituents should have access to the same modern amenities as urban residents. Cities had started the process of gradually paving urban streets and installing modern drainage systems, providing easier access for urbanites and facilitating to-the-door mail delivery many times a day, while roads in the countryside were still muddy, uneven, and unimproved, leaving residents frequently stranded, with only difficult and intermittent access to markets, information, and mail—which typically required a special trip to town to pick up at the post office, rather than home delivery. To support

Federal Aid Road Act of 1916

The Federal Aid Road Act of 1916 firmly established the contours of U.S. highway policy for generations to come. It was politically advanced by a newly assembled coalition of professional technocrats and business interests that grew out of the Good Roads movement and eventually came to be known as the highway lobby. The 1916 act was based on earlier policy experiments that had been carried out at both the state and federal levels, and its core

farm-to-market access and to expand Rural Free Delivery of mail, the Populist Party included a plank in its platform calling for publicly funded rural roads, and the Grange lent its support as well. This rural emphasis of the Good Roads movement, the desire to close the amenity differential between rural and urban, was reflected in the federal legislation that was later enacted, including the 1916 act.

Origins

The 1916 act was not, as is often said, the first federal highway aid program. It was at least partially based on pilot programs that had been enacted earlier, as well as on road-aid programs that had been developed and implemented in some of the states as the movement gained momentum at the beginning of the 20th century. The AAA cosponsored the Second National Roads Convention in Cleveland in 1909, along with the National Grange, the National Association of Automobile Manufacturers, and the American Road Makers Association, which represented civic engineers, highway contractors, and makers of road-building machinery. One year later, in 1910, Logan Waller Page—a federal official—assembled a new umbrella highway lobby organization called the American Association for Highway Improvement to coordinate all these groups. In 1911, Page convened all of these groups for the American Road Congress, a nationwide meeting to devise a coordinated political strategy. President William Howard Taft was the keynote speaker, and within a few months the federal government had enacted an experimental grant to pay for road building.

In 1912, legislation provided funds for the Post Office to pay for one-third of the costs of new rural post roads. This new program would be supervised by Page's agency, which had started as the Office of Road Inquiry and was repeatedly renamed before settling on the name Bureau of Public Roads. This relatively modest program, which authorized \$500,000 in federal aid, had itself been a compromise measure that followed the failure of a much different bill that had been proposed by a congressional Committee on Federal Aid in the Construction of Post Roads. The committee had held hearings, conducted surveys, and researched the road-aid practices of all the states, as well as of many other countries. Their proposal would have authorized the issuance of \$1 billion in 50-year federal bonds, the proceeds from which would be lent

to the states for rural highway construction. This "aid" would have been repaid by the states, so there would have been no net funding contribution by the federal government. The funding model in the successful version of the bill resembled more closely the direct-aid measures recommended by the 1911 Road Congress.

Rural Versus Urban

Though it had taken decades for road-aid advocates to secure federal legislation, success at the state level had come faster. New Jersey had enacted a State Aid Act in 1891, which offered counties grants for one-third of the costs of new roads. When lawmakers in Massachusetts tried to enact a similar law, they added the provision that the new routes must connect to towns and villages, but that aid could not be used for construction of the portions within urban boundaries. Within a decade of New Jersey's first step, seven states had similar programs in place, with more getting in on the game each year thereafter. The antiurban slant of the technical provisions continued to get stronger and more specific. The 1913 legislation enacted by Maine banned the expenditure of any of the aid within a municipality with population over 2,500, and also required a minimum project length of 7 miles. This specific population-size limit would be repeated in the 1916 federal act.

At the federal level, there was no direct road aid authorized until the 1912 law, but there had been federal legislation that provided for research and technical support. During this period, federally funded highway engineers mounted public education campaigns, put together road surveys, spoke with the press and at public events, provided model constitutions for road advocacy groups, and lent their stamp of apolitical expertise to the cause. They framed the public discussion as a set of narrowly conceived technical concerns, setting aside the essential question of who should pay for the new road-building programs. For the time being, the amount of money involved in these programs was relatively modest, and it was easy to disregard this question. Instead, the attention was focused on the need for more and better roads and the need for solutions to be coordinated by well-trained experts. Despite this air of apolitical expertise, programmatic biases were institutionalized that had long-lasting political repercussions, including tight

control of design and routing decisions by federal bureaucrats and funding formulae that steeply favored rural areas and penalized urban regions.

For example, the exclusion of urban roads and streets from these early experimental government road-aid laws seemed, on the surface, to make the modest grant programs more efficient, funding more road-miles by avoiding the most expensive projects. Engineers estimated at the time that each mile of urban highway cost about three times as much as a mile of rural highway. But, because the urban road would have been used so much more, the cost per vehicle-mile would have been much higher on the rural routes. Urban roads were still needed and would have to be built without the same generous national support afforded to roads outside cities.

The 1916 act inherited the explicit rural post road emphasis from the 1912 federal law; it inherited Maine's prohibition on spending within urban areas with population over 2,500 (unless houses were more than 200 feet apart), it inherited the Massachusetts provision that required cities to pay for their portion of intercity routes, and it added new antiurban provisions, beyond these other precedents. It capped grants at \$10,000 per mile, further shortchanging routes that required more lanes or with more complicated routing issues.

The eventual institutionalization of this antiurban perspective by the 1916 act and its subsequent persistence had the long-term effect of collecting billions in tax revenues in urban areas and spending them to develop rural transport infrastructure, simultaneously inhibiting sustained economic prosperity within cities and subsidizing economic development in areas that had previously been sparsely settled.

Regional and Interregional Highways

Not all of the road-building experiments that led up to the passage of the 1916 act had been as centrally coordinated as the postal Rural Free Delivery laws and the state-aid programs. There were also a handful of efforts to put together nation-spanning intercity routes, to allow urban residents and businesses to more easily travel to other big cities. These efforts often took the form of loose associations of individual entrepreneurs and local officials that spanned multiple counties, states, and regions. The best known of these was the Lincoln Highway, which was intended to stretch from New York City to San Francisco.

These efforts differed in both strategy and organization from Logan Page's arm of the road-building movement. Instead of a carefully engineered, tightly organized, and formal group working to enact systematic government road-aid, these individual regional and interregional highways were championed by separate ad hoc associations that would try to coordinate routing, signage, and maps, leaving the actual construction and financing to a patchwork of segment-specific initiatives. Some sections were built by local boosters and tourist-oriented businessmen along the route, others were completed as town or county roads, while others were not ever finished at all (until they were later taken over by the federal-aid highway system created by the 1916 act and its successors).

Since roads like the Lincoln Highway were not intended to be farm-to-market or postal delivery roads, they were denounced by some—especially farmers—as leisure accommodations for economic elites who did not need government help. They did, however, gather support from owners of hotels, gas stations, repair garages, and developers of real estate along the routes, as well as manufacturers and retailers of autos and auto parts. Even as this schism in the Good Roads movement was widening, the group that advocated systematic federal subsidies for farm-to-market highway construction achieved their landmark success: the passage of the Federal Aid Road Act of 1916.

The 1916 Act

The initial draft of the act was submitted to Congress by another of Page's carefully constructed professional associations, the American Association of State Highway Officials. The AAA promptly launched a campaign to support the bill, as did all of the other constituent groups in the highway lobby. Interestingly, the railroads supported the bill too, thinking that it would make it easier for people and goods to get to their stations. Many of these special interest groups tried to pressure Congress to make amendments that would aid their own specific interests. Amid this deluge of lobbying—almost all in support, but sometimes clamoring for conflicting adjustments—congressional leaders turned for advice to Page, as the leading expert in the field. So, in multiple ways, he was the guiding hand behind the act. Arguably, it was his crowning achievement.

One of the most important precedents established by the 1916 act was a direct outcome of Page's experiences traveling around to each of the state capitals and some of the difficulties that he ran into implementing the 1912 Rural Free Delivery program. He had seen up close that many of the states lacked the institutional and legal structures needed to administer federal road-building grants, so he arranged for the act to include a provision that directed every state to create a highway department. His agency laid out the exact required format for these departments and established a standardized procedure for planning, designing, and proposing highways.

The dollar-for-dollar matching grants that were the centerpiece of the legislation would flow only through these new state highway departments, not directly to any localities or to any other public entities, and not directly to any private road builders. Taken as a whole, these mandates prompted, by force of law, an orchestrated expansion of federal and state bureaucracies, supported by much of the of the nation's business community and almost 20 years before the New Deal. Furthermore, by statute and regulation, it placed highway engineers at the center of this new bureaucracy in Washington and in all of the state capitals. While many states already had highway departments, 27 had to make substantial changes to align with the law's new requirements. Eight other states created new departments entirely. Three of them had to pass constitutional amendments in order to comply.

One of the most important provisions of the 1916 act was contained in the technical details of the precedent-setting formula it used for dividing its \$75 million five-year authorization among the states. This same formula, which was based upon a combination of population, area, and existing road mileage, would be used in subsequent highway bills for many decades. By giving the same weight to a mile of single-lane dirt road as a mile along a main four-lane thoroughfare near a city (urban streets did not count at all in this formula) and simultaneously adjusting for each state's geographic size (in effect, twice—once with the area calculation and again with the adjustment for existing nonurban road mileage), the formula introduced yet another funding bias in favor of sparsely settled states at the expense of those states that were more urbanized.

Last, and not least, since the stated focus of the 1916 act was Rural Free Delivery routes, tolls were

forbidden on any roads that received the new federal aid. This, too, became an important precedent, one that would have long-lasting and pervasive impacts that persist to this day. By prohibiting tolls, the act kept the costs of driving well below the costs of providing the road to drive on, fostering the desire of drivers for more and more roads, since they did not need to pay the costs of the benefits that they received when they drove along the new modern highways. This underpricing of road use, along with many of the other core provisions of the Federal Aid Road Act of 1916, were repeated in every successive federal transportation legislation and played a part in rearranging American commuting patterns, housing choices, and lifestyles.

Federal Automobile Safety Standards

By 1965, the automobile had become completely integrated into American life, and the number of vehicles on the road continued to increase significantly each year. Interstate travel also became

more common with the advent of interstate highways. As the number of travelers increased, so did concerns about road safety. That same year, Ralph Nader, a young lawyer and activist who had become impassioned about safety issues in automobiles, published *Unsafe at Any Speed: The Designed-In Dangers of the American Automobile*. The following year, the National Academy of Sciences released a trauma report, "Accidental Death and Disability—The Neglected Disease of Modern Society," in which it was estimated that 49,000 lives had been lost to automobile accidents the previous year. Together, these publications helped focus public attention on forcing automobile manufacturers to design vehicles that included enhanced safety measures. At that time, few vehicles included such features as seat belts, child restraints, or other crash protection measures. Pressure on legislatures led to widespread passage of laws designed to improve automobile safety. The U.S. Department of Transportation (DOT) was established in 1966. That same year, the National Traffic and Motor Vehicle Safety Act established the National Highway Traffic Safety Bureau, which subsequently became the National Highway Traffic Safety Administration (NHTSA). Thus, the groundwork was laid for the implementation of federal automobile safety standards.

Under Title 49 of the U.S. Code, NHTSA is responsible for both establishing and enforcing automobile safety standards and for monitoring manufacturers' recalls of faulty vehicles. Since January 1, 1968, the standards have mandated the manufacture of vehicles that are able to avoid crashes as much as possible and to protect drivers and passengers when crashes do occur.

Basic standards stipulate that vehicles must include such features as windshield defrosting and defogging systems, hydraulic and electric service braking systems, reflective lights, and warning devices such as blinkers and hazard lights. Standards for tire manufacturing and performance are also included. Protections for surviving crashes encompass such features as head restraints, air bags, side impact protection, roof crash resistance, and rear impact protection. These protections also mandate emergency exits on buses and helmets for drivers of motorcycles.

Establishing Safety Standards

Using authority granted in 1966 by the National Traffic and Motor Vehicle Safety Act and the

Highway Safety Act and in 1972 by the Vehicle Information and Cost Savings Act, the National Highway Traffic Safety Administration is responsible for implementing the Federal Motor Vehicle Safety Standards (FMVSS), which initially became effective on March 1, 1967. These standards impact all vehicles manufactured in the United States after January 1, 1968. In order to implement federal automobile safety standards, the NHTSA is charged with reducing deaths, injuries, and economic losses that result from automobile crashes. The NHTSA works closely with state and local governments to reduce accidents and to promote the use of safety measures that have been proven to reduce the number of automobile-related accidents.

The federal automobile safety standards are designed to force automobile manufacturers to build vehicles that are increasingly crash resistant. The standards deal with such measures as seat belts, child restraints, air bags, hydraulic and electric brakes, redesigning mid- and low instrument panels, tires, windshield defrosting and defogging systems, high-penetration resistant windshield materials, crush-resistant roofs, and overall impact protection. All of these measures are intended to make automobiles more resistant to damage when involved in accidents. Despite these measures, approximately 52,000 people die in automobile-related accidents each year. The federal government has consistently faced resistance from car manufacturers who resist the cost involved in increasing safety. That resistance has heightened during periods when the economy is sluggish and when competition from foreign car manufacturers is particularly high.

Impacts of Safety Measures

In 1960, few automobiles contained seat belts, and many people refused to use those that were installed. Even so, the National Highway Traffic Safety Administration estimates that 115 lives were saved by the use of seat belts during that year. In 2004, a report issued by the NHTSA examined the life-saving impact of safety technologies installed in American automobiles between 1975 and 1978, suggesting that approximately 328,551 lives had been saved by safety measures during that period. The overall conclusion was that automobile safety has been steadily rising as automobile manufacturers continue to comply with the federal automobile

The National Highway Traffic Safety Administration estimated that 32 percent of children aged 4 to 7 were not being restrained in car or booster seats in 2009, but by 2011, that number had fallen to 25 percent. In this age group, booster seats reduce injury risk by 59 percent compared to seat belts alone.

safety standards. Some manufacturers have also engaged in voluntary efforts to increase automobile safety, going beyond mandated standards. The number of lives saved by safety standards increased significantly after 1984 when mandatory seat belt laws were enacted in many states. As the number of automobile fatalities and nonfatal accidents decreased, so did the economic impact of those accidents.

In spite of improved automobile safety, approximately 52,000 lives are still being lost in automobile accidents each year. Experts believed that this high cost to human life is often the result of a failure to employ available safety technologies. No example of this is more evident than the use of seat belts. In 1968, federal automobile safety standards began mandating that automobile manufacturers install lap seat belts in all automobiles built in the United States. It took almost two decades, however, before

states began mandating the wearing of seat belts. In 2007, the NHTSA estimated that 63 percent of the 43,000 Americans killed in automobile-related fatalities were not wearing seat belts. The agency also found that adults 65 and over (75 percent) were more likely than other adults (62 percent) to be wearing seat belts when involved in an accident. Young drivers were least likely to wear seat belts, and the NHTSA reported in 2007 that 64 percent of young drivers killed while driving under the influence were not wearing seat belts.

The costs of failing to use available safety features is astronomical, and the NHTSA estimates that hospital costs for unbuckled victims of crashes is 50 percent higher than for those wearing seat belts. The brunt of these costs is borne by society, amounting to some \$26 billion annually and averaging \$580 per person per year. In addition to the high cost of medical care, there is a significant loss in national productivity related to failure to use automobile safety features.

Much attention has been paid to the use of child restraints in the early 21st century. In 2003, 34 percent of children aged 5 and under who were killed in automobile accidents had not been properly restrained. In 2009, the NHTSA estimated that 32 percent of children aged 4 to 7 were not being restrained in car or booster seats as required by most state laws. By 2011, however, the number of children in that age group who were being properly restrained had risen to 75 percent.

The computer revolution that began in the late 20th century has had a major impact on automobile safety, making it possible to gather data immediately before, during, and after automobile accidents in ways comparable to those used in determining the circumstances of airplane crashes. The ability to gather this information has major implications for setting future standards for automobile safety. In 2006, the National Highway Traffic Safety Administration established new standards for gathering information from these event data recorders (EDRs) installed in cars manufactured on and after September 1, 2012.

Federal Aviation Administration

Travel by air has always involved an element of risk; with that risk there has always been need for some form of government regulation and oversight. The

current role of the Federal Aviation Administration (FAA) is best understood in the context of its history, both chronological and historic. With the passage of the Federal Aviation Administration Reauthorization Act of 2009 and the 2011 enactment of NextGen, the FAA is poised to continue to evolve in the foreseeable future, creating an air transportation infrastructure that is the most economical, efficient, and reliable system in the world, with an eye on aircraft safety, air travel security, and environmental sustainability—in the words of its mission, "to provide the safest, most efficient, aerospace system in the world."

Though the history of powered, controlled flight of a heavier-than-air machine goes back to the Wright Brothers' exploit at Kitty Hawk, North Carolina, in 1903, few other people in the United States had actually seen a man fly until 1908, when the Wrights gave their first military demonstration and rival Glenn Curtiss first demonstrated the Aerodrome Number 3, better known as the June Bug, to the public.

In Paris, France, Alberto Santos-Dumont thrilled onlookers in 1906, when he first took to the air in his own powered aircraft, the 14-bis. One year later, throngs of people attended the Grande Semaine d'Aviation de la Champagne, held at Reims, France. By that time, the public was smitten by the miracle of flight. However, the aircraft was an invention in search of a role, be it entertainment or utilitarian. These early machines lacked the power, range, and reliability to carry an economically feasible payload.

It was World War I that saw the first use of the airplane as a potent weapon, first as a means to spy on the enemy and later as a machine to drop bombs and shoot down enemy airplanes and balloons. After the war, worn-out surplus airplanes were providing early air mail service. However, pilots had to rely on navigating by following roads and railways and a magnetic compass. Flying was a very dangerous enterprise; fatal crashes were routine. The first government intervention came with the Air Mail Act of 1925, also known as the Kelly Act. Though this legislation did not cover air safety, it did spur the creation of airline companies to which the government awarded contracts to carry the mail, shifting the costs of flying from the taxpayer to persons purchasing air mail stamps from the Post Office at fixed rates.

Origins

In the following year, the Air Commerce Act of 1926 established the Department of Commerce Aeronautics Branch to enact and enforce rules for the inspection of aircraft for airworthiness and the licensing of airmen that form the cornerstone of the FAA's activities today. Aircraft also were required to display conspicuous identification markings, the forerunner to the FAA N-number aircraft registration today. The agency also oversaw these regulations, along with rules governing navigational aids and aircraft altitude separation; these Civil Air Regulations were the forerunners of the current FAA Federal Air Regulations (FARs).

In 1934, the Department of Commerce renamed the agency the Bureau of Air Commerce; one of its first acts was to encourage the airlines to establish air traffic control (ATC) centers, monitoring air traffic en route between airport control towers. The bureau took control of these two years later, in 1936. The Civil Aeronautics Act of 1938 transferred the responsibilities of the Bureau of Commerce to a new, independent agency, the Civil Aeronautics Authority (CAA), to oversee aircraft and airman certification and to regulate air routes and fares. The authority included the Air Safety Board to conduct accident investigations and recommend ways of preventing future mishaps.

In 1940, President Franklin Roosevelt split the CAA into two agencies: the Civil Aeronautics Administration, which again became part of the Department of Commerce, and the Civil Aeronautics Board (CAB). The administration was still responsible for ATC, airman and aircraft airworthiness certification, enforcing safety regulations, and developing routes, while the CAB oversaw accident investigation and economic regulation of the airlines.

Federal Aviation Act of 1958

In the 1950s, despite the introduction of radar, air traffic control took on greater urgency. Most notable was the 1956 midair collision of a United Air Lines Douglas DC-7 and a Trans World Airlines Lockheed L-1049 Super Constellation, and there would be two more midair collisions before safety legislation could be in place. In addition, the significant difference in air speed between a veteran DC-3 and the new jets entering service became cause for concern. These events were behind the passage of the Federal Aviation Act of 1958, which transferred

the CAA's responsibilities to a new, independent agency, the Federal Aviation Agency (FAA), which oversaw all ATC and aircraft safety measures, as well as aircraft registration and awarding of air routes, in effect combining the roles of the CAA and CAB. When, in 1967, the FAA became part of the Department of Transportation, its name was changed to Federal Aviation Administration, as we know it today.

Evolution

Over the years, the role of the FAA would continue to change. In the wake of the airliner hijackings in the 1960s, it became involved in security measures. After the September 11, 2001, attacks, that task became the responsibility of the then newly formed Transportation Security Administration under the Department of Homeland Security.

Though air pollution and noise were serious problems with early turbojet-powered airliners, especially those that used water injection to provide extra engine thrust for takeoff, it was not until 1968 that the environmental aspects of aviation became part of the FAA's responsibility; this was primarily in response to the supersonic transports being developed in the United States, the United Kingdom, France, and the Soviet Union, and growing pressure from environmental groups. In 1970, the Airport and Airway Development Act gave the FAA responsibility for updating the nation's airports to accommodate the huge increases in civil airline traffic spurred by the jet age, ensuring that ATC centers and airport infrastructure would be safe for the air-traveling public. The Airline Deregulation Act of 1978 phased out the regulation of airline routes and airfares, previously the domain of the CAB. The same agency's accident investigation duties were assigned to the newly formed National Transportation Safety Board (NTSB).

The most spectacular experiment involved a Boeing 720, which the FAA purchased new in 1961 to train safety inspectors of pilots of jet airliners, which had recently entered service. This aircraft, originally N113, reregistered N833NA, was part of a joint exercise in 1984 with the National Aeronautics and Space Administration (NASA) to test the newly formulated antimisting kerosene (AMK), fuel specially treated so as not to ignite in the event of a crash. The airplane was remotely flown at Edwards Air Force Base in what was called the Controlled

This Federal Aviation Administration (FAA) Boeing 720 aircraft was destroyed in 1984 during a controlled crash intended to test a new antimisting kerosene fuel. The plane was remotely crashed at a runway at Edwards Air Force Base near Lancaster, California, in a joint experiment conducted by the FAA and the National Aeronautics and Space Administration.

Impact Project Demonstration (CID); the aircraft was to be flown into a series of metal cutting devices placed at the threshold of the main runway. The aircraft landed short of the runway, slammed into the cutting devices, skidded, and burst into flames. The results of the AMK were disappointing; however, cameras mounted inside the aircraft to film the effect of the impact on crash-test dummy “passengers” did yield some information on ways to make airliner cabins safer and less susceptible to the dangers of fire in the event of a crash. This is probably the only test in which an entirely airworthy airliner was deliberately flown and crashed.

The FAA bought a second jetliner in 1961, a Convair 880, registered N112. In 1981, the aircraft was transferred to the U.S. Navy (Bu161572). In 1995, however, its original owner, the FAA, used the retired aircraft for structural testing of explosive devices under the cabin floor. This was the first such test on an aircraft whose systems were completely operational. The ground test was performed to simulate an internal explosion at high altitude. (Similar tests were performed on scrapped airliners, most notably an ex-LTU Lockheed L1011 and a former Air France Boeing 747.)

As of 2013, the FAA had more than 44,000 employees participating in safety regulation, covering manufacturing and maintaining civil aircraft; airspace and air traffic management, operating a network of ATCs, control towers, and flight service stations and developing air rules, assigning airspace, and controlling air traffic; air navigation facilities onboard aircraft; promoting civil aviation safety abroad; regulating and encouraging the fledgling U.S. commercial space transportation industry; and assisting with civil airplane research, development, and engineering.

Specific programs include the Air Transport and Oversight System (ATOS) to ensure that airlines comply with regulations and safety standards; the Aviation Safety Action Program (ASAP) to promote aviation safety through accident and incident prevention by encouraging voluntary reporting of safety issues and events; the Aviation Health and Safety Program (ASHP); various awards programs for best practices in commercial and general aviation; the International Aviation Safety Assessments (IASA) Program; the National Airshow Program to ensure safety for pilots and spectators at civil and military air shows (including aerobatics);

the National Simulator Program (NSP); managing the storage and retrieval of records; Safer Skies, a major initiative of the General Aviation Joint Steering Committee (GA-JSC) to reduce fatal accidents among private (general aviation) aircraft; the Suspected Unapproved Parts (SUP) Program to ensure only certified replacement parts be used by air carriers and third-party maintenance facilities; the System Approach for Safety Oversight Program (SASO); and maintaining an effective Whistleblower Protection Program to ensure that anyone reporting unsafe or illegal conditions will be protected against any retribution.

With an eye on the future, the Century of Aviation Reauthorization Act of 2003 initiated the concept of NextGen, the Next Generation Transportation System, a multiagency effort to develop the safest, most efficient, and most secure aviation system possible by 2025. The first document, *Destination 2025*, outlines how the FAA is to accomplish five goals: move to the next level of safety, create the workplace of the future, deliver aviation access through innovation, sustain our future, and advance global collaboration. These documents and more will ensure the FAA fulfills its mission, through its vision, “to reach the next level of safety, environmental responsibility and global leadership” through its fivefold set of values: “Safety is our passion; Excellence is our promise; Integrity is our touchstone; People are our strength; Innovation is our signature.” These core values are also the basis of NextGen, enacted in 2011 as “a comprehensive overhaul of our National Airspace System to make air travel more convenient and dependable, while ensuring your flight is as safe, secure, and hassle-free as possible.”

The plan maps out what the agency needs to do to address economic, environmental, safety, security, and communication concerns. It is noteworthy that the FAA has restored one example of its most memorable aircraft (and the first aircraft to make commercial aviation profitable without government air mail subsidies), the Douglas DC-3 (TC-47K), N34, as a flying museum to teach the next generation about the values of the FAA and the history upon which this critical agency was built.

Federal Aviation Administration Reauthorization Act of 2009

The Federal Aviation Administration (FAA) is an agency of the U.S. Department of Transportation.

It is responsible for regulating and supervising all aspects of civil aviation in the United States.

On February 9, 2009, the FAA Reauthorization Act was introduced in Congress as H.R. 915. It passed the House of Representatives by a vote of 277 to 136 on May 21, 2009. It included provisions for the Airport Improvement Program, studies of pilot fatigue and of runway lighting and safety, increases in fuel taxes for general-aviation planes, modernization of the air traffic control system, and major increases in passenger facilities fees. It also contained requirements for subsonic noise reductions and labor provisions, both of which were controversial. One provision covered the airport fire departments and their firefighters, who usually belong to a firefighters union. The president of the Memphis International Airport publicly stated that the bill's expansion of airport fire departments, increasing staff and equipment, was not acceptable.

The other significant labor provision (section 806), was widely viewed as favorable to labor organizing efforts or as a union payback to opponents. The FAA Reauthorization Act carried a provision that affected FedEx, one of the major courier delivery services in the United States. Based in Memphis, Tennessee, the FedEx Corporation was originally known as Federal Express and became FedEx in 2000. FedEx began with the delivery of packages using ground transportation, but its founder Fred Smith invented the concept of express delivery. For example, using the FedEx hub-and-spoke model of delivery, a package from Dallas bound for New York is delivered to the hub at Memphis by an airplane that returns on its Dallas-Memphis spoke, while the package is transferred at the hub to a plane from New York that returns on its spoke.

The system enabled FedEx to become a global leader in overnight deliveries of a variety of packages—especially those that may be low in value but are high in priority. It is a global transportation company that operates worldwide. It was also successful in preventing unionization of its business. One way to accomplish this was to identify and hire drivers as independent contractors. It does not engage in direct supervision of its drivers' work performance. It does provide suggestions and best practices for performances of assigned tasks, but it does not have the authority to require compliance with its suggestions under its independent driver agreements.

The use of independent contractors as drivers by FedEx was challenged by the Internal Revenue Service (IRS), which in 2008 reversed its classification of FedEx drivers as independent contractors, saying the classification had been in error. They were actually employees, the IRS claimed, and therefore FedEx owed more than \$300 million in back taxes. The IRS later revised its decision and returned to its original classification of FedEx employees as independent contractors. However, other political forces were at work, and among them were unions, rival United Parcel Service (UPS), and states eager to collect taxes from FedEx.

FedEx described the bill as a legislative bailout for those who wanted to gain money from FedEx and those who wanted to harm its competitive position. The provision affecting FedEx authorized its drivers to organize collective bargaining units under the terms of the National Labor Relations Act (NLRA) and eliminated the requirement that any organizing efforts be conducted according to the rules of the Railway Labor Act (RLA).

The dispute in part involved UPS, with support from the International Brotherhood of Teamsters and the nonairline personnel working at FedEx. The UPS ground workers were organized under the NLRA provisions, which allowed organization of union units at work sites on a site-by-site basis. The airline workers of UPS were covered by RLA rules. In contrast, all FedEx drivers had been covered by the rules of the RLA, which required unionization nationally. Because the RLA rules made it harder to unionize, there was a lower rate of unionized workers.

In public statements, FedEx said that if the bill were to pass the Senate and become law, those who rely on next-day delivery service for medicine, critical parts, or essential goods would pay the price of this political manipulation that would reduce competition; it would eventually expose the public to the effects of strikes involving union workers at FedEx, and the effects would disrupt essential overnight or time-sensitive deliveries of high-value shipments. The Teamsters responded with an Internet campaign that argued that FedEx drivers were not airline pilots, therefore FedEx's ground drivers should be covered by the NLRB and not by the RLB.

The impact for rival UPS would have been insignificant because its drivers had been organized and operated as members of the Teamsters Union.

Those opponents of FedEx assumed that unionization would increase costs for FedEx and thereafter reduce its competitive advantage to the benefit of UPS and others. Consequently, some pundits began to call the bill a brown bailout, referring to the brown uniforms of UPS drivers.

UPS had engaged in lobbying efforts for the adoption of the FAA Reauthorization Act of 2009 (H.R. 915). FedEx's lobbyists used the term *bailout* to characterize the law as giving an economic subsidy to a competitor that was inefficient. Critics of the FedEx lobbying effort claimed that the use of the term *bailout* was unethical.

Regardless of criticism from independent political observers, the term *bailout* was a buzzword used frequently in 2008 to describe the Emergency Economic Stabilization Act of 2008. Bailouts providing subsidies for failing companies and government institutions were authorized. It may have been unethical to apply the term to benefits for UPS, which was not in financial trouble, but it was very effective politically in framing the public debate for FedEx. Other interest groups also supported FedEx's position and lobbied Congress to defeat the bill.

On June 1, 2009, the Senate received and introduced the House version of H.R. 915. It was read twice and then referred to the Senate Committee on Commerce, Science and Transportation. The bill was passed on March 22, 2010, in a Senate version. This version did not include the provision that FedEx opposed. Without the controversial labor provision, the bill was sent to an ad hoc conference committee that was to reconcile the differences between the two versions of the bill, as constitutionally required in the bicameral system of Congress. The deadline for reconciliation was June 30, 2010; however, the deadline passed without reconciliation being accomplished, which killed the bill, preventing its enactment as law.

In the legislative work on the FAA Reauthorization Act, Senator Claire McCaskill (D-MO) inserted language in the bill to address the problems associated with outsourcing airline maintenance to foreign repair stations. The legislation addressed the fact that work performed at foreign repair stations created economic issues as well as safety issues. Also it would also close loop holes that were allowing threats to national security.

The bill was amended to provide protection for whistleblowers from retaliatory actions when they

reported unsafe airline practices. The protections would be supported by actions of the FAA's Office of Whistleblowers.

In 2012, the 112th Congress amended the Federal Aviation Administration Reauthorization Act of 2009 in an appropriations bill. It was published on February 14, 2012, as Public Law 112-95 (126 STAT 11). It provided funding, support for next-generation aircraft emerging from research and experimental testing and the airport systems needed to handle them, ways to collect passenger facility charges, airport improvement programs, and more.

Federal Highway Act of 1921

The Federal Highway Act of 1921 was more than just the routine reauthorization of the groundbreaking Federal Aid Road Act of 1916. It contained significant adjustments and enhancements to the earlier legislation, stabilizing the experimental federal-aid highway grant program, which had faced

logistical and political difficulties. By building on the precedents established in 1916 and by introducing important new precedents, the 1921 act initiated a golden age of highway building in the United States that lasted for half a century.

The most important provision of the act was the requirement that each state formally designate 7 percent of its total road mileage as “federal-aid highways,” further divided into primary routes and secondary routes. This marked the first official creation of a nationwide system of hierarchically designated highways. The act formally defined primary routes as interstate roads and mandated that each state spend at least 60 percent of its federal-aid allocation on these projects. Furthermore, each state was required to develop official maps that designated 3 percent of their total road mileage as these primary routes. The other federal-aid highways in each state, making up 4 percent of the total, were defined as secondary routes that served intercounty traffic in rural areas and were allocated the remaining 40 percent of the federal grants. Urban roads were still excluded from federal support, in keeping with the provisions of the 1916 act, which had been exclusively focused on farm-to-market and rural post roads.

National Highways

This new provision not only got the nation started toward a coherent system of nationwide roads, it also served two important political purposes. First, it re-established consensus by reuniting the battling factions of the highway lobby. Since the 1916 act had passed, with its exclusive focus on rural routes, the proponents of long-distance interstate roads had become increasingly critical of the federal-aid program, pushing for alternative approaches to road building. A proposal for a national highway commission—rather than the decentralized model that had been created in 1916, made up of state highway departments supported by federal grants—had been gaining support.

Meanwhile, other groups continued to move forward with ad hoc interregional highway initiatives like the Lincoln Highway Association, which been formed to stitch together a road from New York to northern California, via Pittsburgh, Indianapolis, Chicago, Omaha, and Salt Lake City. Another group was trying to assemble a route called the Dixie Highway, from Chicago to Miami. A third group

pushed for the Robert E. Lee Highway, from New York to New Orleans. A fourth group tried to enlist political support for the John Bankhead National Highway, which would go from Washington, D.C., to San Diego by an indirect route passing through Atlanta, Charlotte, Memphis, Birmingham, and Little Rock—not to be confused with the proposed National Highway from New York to Atlanta, or the competing group pushing for the so-called Capital Highway from Washington to Atlanta. The 1921 act ended this debate, responding to the clamor for long-distance highways by formally establishing a national highway system of primary routes that would be coordinated and funded by a federal agency in partnership with the state highway departments.

Second, by expanding the scope of the existing grant program, and by mandating additional technical tasks, the 1921 act strengthened and further entrenched the existing institutional structures. The state highway departments and the federal Bureau of Public Roads (BPR) became larger and stronger as they geared up for mapping the new national network of primary and secondary routes. Furthermore, the 1921 act directed the BPR to promulgate minimum paving standards, minimum roadway widths, maximum grades and curvatures, and other technical rules. Overall, while the 1916 act had produced a highly structured highway funding mechanism and forced the creation of a new bureaucracy, it was the 1921 act that confirmed and buttressed these institutional arrangements.

Antiurban Approach

The 1921 act repeated the antiurban slant that had been embedded in earlier highway legislation. Not only did it continue to forbid any grants to roads in urban areas, it also renewed the cap on aid-per-mile, effectively providing lower support levels for routes that needed to be wider or passed through areas with higher land costs. The cap was raised, from \$16,000 per mile in the 1916 Act, to \$20,000 in the 1921 Act, but construction costs had gone up by almost 90 percent during the same period, so this was not a substantial increase.

Furthermore, the antiurban slant of the nascent federal highway program was increased by the 1921 act. On its face, the act seemed to continue the 1916 act’s practice of providing matching grants to the states on a 1:1 basis. In other words, the federal

government would provide 50 percent of the funds for approved road projects. But, one of the technical provisions of the 1921 act adjusted this matching ratio by taking into account the federally owned land in each state. Ostensibly, this provision was justified on the grounds that the federal land was not subject to local taxes. But, in effect, it provided much more attractive terms for western and rural states, compared to eastern urbanized states. For example, instead of the 1:1, or 50–50, matching arrangement enjoyed by northeastern states, Nevada enjoyed an 8:1 matching ratio, meaning that the federal government paid for about 88 percent of the costs. Utah benefited from a matching ratio of 3:1 (a 75–25 split). Wyoming's ratio was 2:1, for a 67–33 split. Arizona, Colorado, Idaho, and New Mexico also benefited from substantially better terms.

Thomas MacDonald

Much of the behind-the-scenes work on the 1921 act was carried out by Thomas MacDonald. MacDonald had taken over as the top federal highway official in 1918 after the death of Logan Page. At that time, the federal-aid highway grant that had been created by the 1916 act and had been administered by Page's Office of Public Roads was struggling with rapidly escalating costs, fragmenting political support, and partnership with underdeveloped state highway departments. Under MacDonald's leadership the agency, now renamed the Bureau of Public Roads, rebuilt political consensus, acquired increased funding, and worked assiduously to augment the state highway departments. MacDonald had formerly been in charge of the Iowa department, so he knew what types of technical support the states needed from Washington. In 1919 and 1920, the program began to achieve some results, so that by the time the 1921 act was proposed, MacDonald could point to a successful track record.

Funding

The entire program was funded without any federally imposed charges on motorists. Tolls were explicitly banned from all roads funded with the federal-aid grants, and there was not yet a federal gas tax. MacDonald was known to say that tolls were an infringement on individual freedom. However, since at this time a very small portion of Americans owned automobiles or even knew how

to drive, and more than half of the country lived in urbanized areas that would not benefit from the new federal grants, the entire program amounted to a transfer of funds from urban to rural and from nondrivers to drivers.

While the 1916 act had initially provided for \$75 million in grants over five years, it quickly became clear that this sum was insufficient. In 1919, MacDonald was able to secure an additional \$50 million, followed by \$75 million each in 1920 and 1921. The 1921 act provided for \$75 million per year for five years. Not only was this five times the amount funded in 1916 but it also allowed for multiyear project commitments, and MacDonald would not need to return to Congress each year to ask for an annual budget allotment.

The new flow of funds, as well as MacDonald's careful organizational and political work, soon achieved results. By the end of 1920, the 1916 program had produced almost 3,000 projects, covering almost 30,000 miles. While all of these were disconnected farm-to-market roads that did not yet form a coherent national network, the program nevertheless demonstrated that the new federalist system, with central funding and coordination, in partnership with state-based construction and implementation, could produce consistent results.

The 1921 act, with its new emphasis on building a rudimentary system of nationwide long-distance routes while continuing the work on farm-to-market roads, was the second-generation version of the 1916 program. Within a decade of its passage, the 1921 act had put a designated federal-aid road within 10 miles of 90 percent of the U.S. population.

State and Local Burden

As the program expanded in size and scope, it became more expensive for state and local governments to keep up with their funding obligations. They started to take on debt in order to raise their money to pay their share. Furthermore, the 1921 act included an obligation that the states provide adequate resources to maintain the federal-aid highways. The federal grants could be used only for new construction, not for maintenance or repair. This led to a substantial financial burden, and the states often turned to gas taxes, license fees, and vehicle registration fees.

Still, even with the emergence of these new user fees, it was estimated that motorists were still paying

less than a third of the \$1.5 billion that was being spent on roads and streets nationwide by the mid-1920s. Within city limits, the burden fell almost entirely on local property taxes, because of the exclusion from the federal program and because the states could barely keep up with matching their federal grants and paying for maintenance of their designated federal-aid primary and secondary routes.

The national highway map that was developed under the 1921 act introduced the practice of standardized route numbers that are still used today, with even-numbered routes going east-west and odd-numbered routes going north-south. This convention would later be duplicated for the Interstate Highway System.

Federal Highway Administration

Headquartered in Washington, D.C., and operating under the auspices of the U.S. Department of Transportation, the Federal Highway Administration (FHWA) is responsible for exercising oversight of the construction, maintenance, and preservation

of all highways, bridges, and tunnels in the United States. The FHWA provides technical support in these areas, working closely with state departments of transportation and with those involved in operating and maintaining federally owned lands. The FHWA's annual operating budget of \$30 billion is generated by excise taxes on fuel and motor vehicles. Through the Federal Aid Highway Program and the Federal Lands Highway Program, the FHWA also provides financial assistance to state and local governments and federal lands. The latter area encompasses national parks, national forests, Native American tribal lands, and all other federal lands. The FHWA is also involved in partnerships with federal and state agencies, nonprofit organizations, and the private sector, working together to carry out assigned tasks and promote the needs of the highway sector and the American people.

The Federal Highway Administration is involved in a range of core fields, and all have a major impact on the transportation sector. In the area of highways, it is responsible for overseeing highway funding, road operations and congestion, roads and bridges, road users, and highway safety. The FHWA's authority also extends to exercising oversight of highways at border crossings. Protecting the environment continues to be of major importance, and the FHWA has responsibilities in the areas of supporting wetland banking, restoring habitats, engaging in historic preservation, improving air quality, cutting down on noise pollution, mitigating the negative impacts of climate change, providing facilities for pedestrians and bicyclists, and protecting wildlife by providing designated wildlife crossings.

History

In 1893, as the sight of automobiles was becoming more common in the United States, the Office of Road Inquiry was established. In 1905, as the number of cars on American roads continued to increase, the name of the agency was changed to the Office of Public Roads, which operated under the auspices of the U.S. Department of Agriculture. A decade later, the name of the organization was changed to the Bureau of Public Roads. The name of the agency was again changed in 1939 when it began operating as the Public Roads Administration under the Federal Works Agency. That agency was abolished in 1949, and the transfer to the Department of Commerce signaled a name change

back to the Bureau of Public Roads. On October 15, 1966, the Federal Highway Administration was established. The following year, the FHWA took on all responsibilities previously assigned to the Bureau of Public Roads.

Within the context of passing the Federal Highway Act of 1938, Congress made its first official recommendation to build an interstate system designed to cross the United States in all directions, bringing all the states together and connecting them with Canada to the north and Mexico to the south. The act instructed the Bureau of Public Roads to investigate the possibility of building three superhighways that stretched across the country from east to west and three that would traverse the nation from north to south. Oversight of those first interstate highways—as well as the many others built over time—came to be one of the major responsibilities of the Federal Highway Administration.

Research and Technology

Major research projects overseen by the Federal Highway Administration include the Turner-Fairbank Highway Research Center (TFHRC) and FHWA Priority Market-Ready Technologies and Innovations. Turner-Fairbanks Highway Research Center, located in McLean, Virginia, houses the FHWA's Office of Research, Development, and Technology. The facility conducts both applied and exploratory research in areas such as vehicle-highway interaction, human-centered systems, and intelligent transportation systems.

FHWA Priority Market-Ready Technologies and Innovations coordinates research and technology not only for the FHWA but also for state research and technology programs, the National Cooperative Highway Research Program, University Transportation Center programs, the Intelligent Transportation Systems program, and various private-sector and nonprofit research and technology programs. The facility also cooperates with international agencies such as the Organisation for Economic Co-operation and Development (OECD) and the Federation of European Highway Research Laboratories.

Cooperative research is integral to the FHWA's mission to make American roads among the safest and most technologically advanced in the world. In 1997, for instance, the Federal Highway Administration joined the Standing Committee

A truck enters the Hanging Lake Tunnel on Interstate 70 in Colorado in 2008. The Glenwood Canyon project that included the tunnel was one of the last pieces of the U.S. Interstate Highway System to be finished, with construction beginning in 1980 and ending in 1992, at a cost of \$490 million.

on Highway Traffic Safety of the American Association of State Highway Transportation Officials (AASHTO), the National Highway Traffic Safety Administration (NHTSA), and the Transportation Research Board (formerly the Highway Research Board) to develop the AASHTO Highway Safety Plan to address a broad spectrum of issues related to improving travel on U.S. highways. One core research area that arose from the joint project was the commitment to address the needs of older drivers as baby boomers continue to age over the coming decades.

Innovation

The Federal Highway Administration has long been recognized for its willingness to try new technologies and for successfully implementing those that prove beneficial. In 1988, the FHWA created the Strategic Highway Research Program. Two of the most successful innovations to come out of that

initiative were the widespread use of Superior Performance Asphalt PAVements (Superpaves) and improved methods for maintaining highways during winter months in areas that experience harsh weather conditions. In 2004, the FHWA established the Highways for LIFE fund, which is implemented through congressional funding, to assist state departments of transportation in implementing innovative ideas.

In order to carry on the work begun by the first Strategic Highway Research Program, the FHWA launched the Second Strategic Highway Research Program (SHRP 2) in 2005 with funding from Congress. The goal of the second initiative is to turn innovative ideas into successful practices. The head of the FHWA is heavily involved in the program, and the deputy administrator provides daily leadership. Each state has created a Transportation Innovation Council, and these groups make decisions about the particular innovations that meet the needs of individual states.

Technologies instituted through SHRP2 include the use of warm-mix asphalt, the employment of geosynthetic reinforced soil-integrated bridge systems, and the inclusion of prefabricated bridge elements for use in bridge construction and repair. Additionally, 40 states have begun using the Safety Edge, which shapes the pavement edge at a prescribed angle during construction, resulting in increased safety for motorists.

Federal Motor Carrier Safety Administration

The Federal Motor Carrier Safety Administration (FMCSA) is a federal regulatory agency that was established January 1, 2000. Headquartered in Washington, D.C., it regulates the trucking industry in the United States and employs over 1,000 people in all 50 states and in the nation's capital. Its regulatory work is focused on improving the safety of commercial motor vehicles (CVM) and truck drivers through the promulgation and enforcement of safety regulations.

The FMCSA was authorized by the Motor Carrier Safety Improvement Act of 1999. It is a separate administration within the U.S. Department of Transportation. Previously, it had been a unit of the Federal Highway Administration. It is organized into three units called "ART," from the name of the subunits of the Offices of Analysis, Research, and Technology. Its primary mission is to reduce the number of accidents, injuries, and fatalities involving large trucks and buses on America's highways.

There are 14 key programs operated by the FMCSA: Border and International Safety, Commercial Driver's License Program, Enterprise Architecture, Federal Motor Carrier Safety Regulations (FMCSRs), Hazardous Materials Regulations (HMRs), Household Goods Program, Medical Program, Motor Carrier Safety Assistance Program (MCSAP), Motor Carrier Safety Identification and Information Systems, New Entrant Safety Assurance Process, Passenger Carrier Program,

Performance and Registration Information Systems Management (PRISM), Research and Analysis (R&A), and the Safety Education and Outreach program. These programs are part of the FMCSA's strategy to save lives.

Safety Programs

The Border and International Safety program is part of FMCSA's work in developing uniform standards or at least compatible motor carrier safety requirements and procedures throughout North America. It works with the governments of Canada and Mexico to ensure that Mexican and Canadian drivers of commercial motor vehicles in the United States meet the same safety standards as do American drivers.

The Commercial Driver's License Program develops, monitors, and supervises compliance with federal commercial driver licensing standards. These are the standards that commercial motor vehicle (CMV) drivers must meet to get a commercial drivers' license (CDL). The standards set by the FMCSA are the minimum standards that are uniformly applied across all of the jurisdictions of the United States. States are free to set higher standards and to manage the examination and granting of CDLs to applicants.

The FMCSA's Enterprise Architecture is a program that seeks to develop information technology systems. The "plan" or "blueprint" that the FMCSA is developing is its emerging guide to how develop and manage information technology. The plan is called Enterprise Architecture by FMCSA.

The Federal Motor Carrier Safety Regulations (FMCSRs) program is being developed and maintained in order to enforce federal regulations. The regulations are promulgated and enforced in order to promote carrier safety, industry productivity, and new technologies. The safety regulations are a baseline for safety requirements for operating commercial vehicles. The regulations also establish rules for drivers, carriers, vehicles, and vehicle equipment.

The Hazardous Materials Regulations (HMRs) program is designed to safeguard the public from dangers posed by the transportation of hazardous materials. The HMR rules address the classification of hazardous materials, proper packaging, employee training, hazard communication, and operational requirements.

Moving van companies are regulated under the FMCSA's consumer protection program, which it calls the Household Goods Program. Companies

that move household goods are required to register with the FMCSA, which uses a Web site (www.ProtectYourMove.gov) to assist consumers moving across state lines. It also has a toll-free hotline (1-888-368-7238) and a Web site (nccdb.fmcsa.dot.gov) for consumer complaints on interstate movers.

The FMCSA Medical Program promotes safety on the nation's highways by setting policies and standards for the health of CMV drivers. FMCSA publications and medical regulations seek to ensure that drivers operating in interstate commerce are healthy and physically fit to drive safely.

The Motor Carrier Safety Assistance Program (MCSAP) is a federal grant-in-aid program that provides states with financial assistance to hire staff and implement strategies to enforce the Federal Motor Carrier Safety Regulations and its Hazardous Materials Regulations programs. MCSAP funds are used to conduct roadside inspections and review motor carriers' compliance with FMCSRs and HMRs. MCSAP funds promote detection and correction of commercial motor vehicle safety defects, commercial vehicle driver deficiencies, and unsafe motor carrier practices before they become contributing factors to crashes and hazardous materials incidents.

The Motor Carrier Safety Identification and Information Systems program provides safety data. The data include state and national crash statistics and current analysis results, as well as detailed motor carrier safety performance data. The information is provided to both the industry and the public. The data is used in enforcement because it allows federal and state enforcement officials to target inspections. It also directs inspectors to areas where investigations can focus on higher risk carriers, vehicles, and drivers.

The New Entrant Safety Assurance Process allows new companies to enter the CMV market, but only after careful inspection. New companies must apply for a license and receive a USDOT number. The program also ensures that drivers and new companies entering the CMV market are knowledgeable about federal motor carrier safety and hazardous materials regulations. New entrants are monitored for an 18-month probation period. During that time the new carrier has to pass a safety audit. It also has to maintain safe operations to receive permanent USDOT registration. If a new motor carrier fails to maintain adequate basic safety

management controls, it may have its temporary USDOT registration revoked.

The Passenger Carrier Program supervises implementation of key actions within the U.S. Department of Transportation's Motorcoach Safety Action Plan. The Passenger Carrier Program is administered by FMCSA's Commercial Passenger Carrier Safety (PCS) Division, which is housed within the agency's headquarters. The mission of the PCS Division is to reduce crashes, injuries, and fatalities involving passenger-carrying commercial motor vehicles while ensuring the safe and accessible transportation of bus passengers. The PCS Division is responsible for administering the Americans with Disabilities Act Compliance Program for over-the-road bus companies. It also develops the agency's policies and programs for passenger carrier-related matters. And it participates in all passenger carrier-related activities, including rulemaking, research, data management, and outreach projects.

PRISM

The Performance and Registration Information Systems Management (PRISM) is a joint effort of the federal and state governments to ensure that commercial motor vehicle drivers drive safely. Safe performance is therefore a requirement for obtaining and keeping a commercial vehicle registration for a company, as it is for a CDL driver. The PRISM program links federal motor carrier safety records to every state's vehicle registration program. CMV companies have an assigned USDOT number that must be displayed on its vehicles. Each vehicle can be identified and its safety record assessed to determine the carrier is meeting safety standards. The determination of the carrier's record is made before the carrier can be issued license plates for its vehicles. The program allows safety performance to be monitored continuously. If a carrier fails to meet safety standards, its license to operate CMVs in interstate commerce may be revoked and the company will then no longer be able to register its vehicles. The use of the PRISM program is playing a major role in removing unsafe drivers and high-risk companies from the nation's highways.

A growing number of accidents involving commercial vehicles led to the development of PRISM. Interstate carriers were increasing rapidly in number, and with the increase in carriers came a corresponding increase in CMV accidents. PRISM

has been able to increase federal and state safety efforts with efficiency and effectiveness by quickly and accurately identifying highest risk carriers who have the most accidents. These are the highest risk carriers. Compliance review, roadside inspections, and other issues are efficiently examined. Scarce resources are used more carefully in compliance reviews and roadside inspections.

Motor carriers are required through the PRISM program to improve their identified safety deficiencies. If they do not comply, they will experience a series of increasingly stringent sanctions. The ultimate sanction is a Federal Out-of-Service order. The Federal Out-of-Service order is accompanied by concurrent state registration suspensions. To date, the PRISM program has been an effective way to motivate motor carriers to attend to safety issues and to make all changes necessary to eliminate safety deficiencies and compliance failures.

Congress mandated the PRISM program as a pilot project in the Intermodal Surface Transportation Efficiency Act of 1991. The pilot program was developed by the FMCSA and the state of Iowa. Four other states (Colorado, Indiana, Minnesota, and Oregon) participated along with Iowa in the pilot project. The pilot project ended in 1997 after it demonstrated that sanctions applied through state commercial vehicle registrations were effective tools for increasing motor carrier safety. With positive results in hand, Congress authorized funding for a national expansion of the PRISM program in the Transportation Equity Act for the 21st Century (TEA-21). Beginning with fiscal year 2006, more funding has been authorized for the PRISM program in the Safe, Accountable, Flexible, and Efficient Transportation Equity Act: A Legacy of Users (SAFETEA-LU). The Moving Ahead for Progress in the 21st Century Act (MAP-21) (Public Law 112-141, Sections 32602 and 32603) has authorized PRISM program funding for fiscal year 2013 to 2014.

Other Research and Outreach

The Research and Analysis (R&A) program seeks to study basic questions in order to develop applicable knowledge for road safety. The goal is to develop new methods and technologies that will make trucks and buses safer and more secure. Actions to achieve its research goal include conducting rigorous studies aiding the development of a science of vehicle safety. The basic research gains are used to

develop innovative best practices for drivers, vehicles, and carrier operations.

Technologies are being developed that can be deployed. Researchers examine traffic wrecks, injuries, and fatality events in order to develop a program that contributes to making vehicle operations—especially commercial vehicle driving—safe and secure. The research projects seek to identify techniques that will ensure that commercial drivers meet the physical and mental demands of their work. Other research is aimed at discovering ways to improve vehicle performance in a safe manner through vehicle-based safety technologies. Research supports efforts to apply safety management principles to enhance safe driving. Studies of the best management and communication practices are conducted to aid in enforcement of carrier-related regulations. Some research seeks to advance safety through information-based initiatives and information systems and technologies. Studies to improve security benefits to commercial carriers are also conducted. Finally, the most fundamental element is addressed by studies that focus on motivation toward excellence. The professional goal that the FMCSA has set for itself is to improve its service to its customers and stakeholders.

The Safety Education and Outreach program is focused on education. The program uses various educational strategies to increase compliance with safety regulations. The goal is to reduce commercial vehicle accidents. Its educational messages are aimed not only at commercial vehicles but at all roadway users, including pedestrians, bicyclists, and the driving public.

The Compliance Safety Accountability (CSA) program was begun in 2008 in field tests in Colorado, Georgia, Missouri, and New Jersey. In 2009 Delaware, Kansas, Maryland, Minnesota, and Montana were added to the field tests. The CSA program replaced the “SafeStat” model that had been used to measure safety performances. In the summer of 2010 data was available so that both carriers and drivers could see their records in the Behavior Analysis and Safety Improvement Category (BASIC). BASIC is the database where safety information is stored. The results could be contested after posted in BASIC.

The CSA program was challenged in federal court by the National Association of Small Trucking Companies, the Expedite Alliance of North

America, and the Air and Expedited Motor Carriers Association, organizations claiming to represent about 2,750 small carriers, who alleged that FMCSA has not followed proper procedures before publishing the data. Their petition for an injunction was, however, denied by the U. S. Court of Appeals for the District of Columbia.

Federal Railroad Administration

The railroad industry in the United States plays a critical part in the nation's economy and represents perhaps its most effective means of transportation. Passenger volume carried by the U.S. rail system can be measured in the hundreds of millions (650 million in 2011). Passenger service represents a substantial investment and service but happens to be the weakest part of rail service in the country. The most important aspect of the rail system, and the one in which the United States is a world leader, is the transportation of freight. American freight transport exceeds both the scale and effectiveness of anywhere else, especially compared to Europe, where trucks are used to ship a large portion of freight. American rail companies have also transported freight over the decades at decreasing costs to their customers.

In addition to the service it provides to the national economy by moving passengers, commodities, and goods, the American rail industry also contributes to the economy through its investments in infrastructure and the salaries it pays its workers. As a major component of the nation's transportation infrastructure and economy, it is regulated and monitored by the U.S. government, specifically, the Federal Railroad Administration.

Role and Organization

As one of several agencies that compose the U.S. Department of Transportation (USDOT), the Federal Railroad Administration (FRA) is the governmental regulatory agency that oversees all railway operations in the United States. The FRA's stated mission is to "enable the safe, reliable, and efficient movement of people and goods for a strong America, now and in the future." Currently, the FRA regulates more than 760 railroads throughout the country.

The FRA has several areas of responsibility of which its focus on safety is the most important. It

issues and enforces all federal safety regulations pertaining to railroads. It also exists as a research organization concentrating on safety, policy, technology, and other issues. It administers railroad assistance programs. Further, the FRA has special responsibility for the maintenance and improvement of rail service in the Northeast Corridor (essentially the Boston-to-Washington rail route).

The FRA came into being in 1966 as a result of the Department of Transportation Act of 1966, which created the USDOT and its subsidiary organizations. It assumed the safety and regulatory activities for rail transport that had previously been part of the oversight of the Interstate Commerce Commission. As of 2012, the FRA's staff numbered approximately 900, with an annual budget in excess of \$1.6 billion. Its chief, the administrator, reports directly to the secretary of transportation and is the principal adviser on all railroad matters to the secretary. The administrator is the principal representative of the U.S. Department of Transportation on railroad affairs.

The FRA is organized into offices that support internal operations as well as the core responsibilities of the agency. The first of these offices is the Administrator's Office. According to its mission statement, the Administrator's Office has overall responsibility for federal railroad policy (passenger and freight), legislative matters, safety issues and regulations, and the creation of a positive working environment within the administration.

Other support organizations in the FRA include the Offices of Communications, Civil Rights, Public Engagement, and Administration. The chief financial officer is responsible for the Office of Financial Services and the Office of Budget. The chief counsel oversees the Safety Law and General Law divisions. The remaining two offices are directly concerned with railway issues. These are the Office of Railroad Safety and the Office of Railroad Policy and Development.

The Office of Railroad Safety is divided into three main sections. These are the Office of Safety Analysis, the Office of Safety Assurance and Compliance, and the Offices of the Regional Administrator. There are eight of these FRA Regional Offices. The Office of Safety Analysis comprises 14 areas of responsibility, each assigned to a division. Seven of these (safety regulating analysis, highway rail crossing and trespassing, risk reduction, railroad safety technical

training standards, state rail safety participation, railroad safety information management, and safety program management) are managed by the Office of Safety Analysis. The second area under the Office of Railroad Safety is the Office of Safety Assurance and Compliance, which comprises divisions that have responsibility for operating practices; hazardous materials; industrial hygiene; motive power and equipment; track, signal, and train control; and rail and infrastructure.

The third area under the Office of Railroad Safety consists of the eight regional safety field offices. These offices conduct a wide range of safety-related operations. The staff in these regional offices conduct safety inspections of railroads (areas inspected are those within the general areas covered by the office's safety divisions and include motive power, tracks, signals, hazardous materials, and structures). Regional safety staff members assist the National Transportation Safety Board (NTSB) in the investigation of accidents, act as expert witnesses, and investigate the failure of safety devices. The staff also support the efforts to create and enforce "Quiet Zones" (crossings where trains cannot sound their horns in order not to increase noise in residential areas). The field offices are located in Cambridge, Massachusetts (Region 1), Crum Lynne, Pennsylvania (Region 2), Atlanta, Georgia (Region 3), Chicago, Illinois (Region 4), Ft. Worth, Texas (Region 5), Kansas City, Missouri (Region 6), Sacramento, California (Region 7), and Vancouver, Washington (Region 8).

The regional office operations are managed by the chief safety officer, who oversees the regional administrators, and include safety inspector training (for both state and federal inspectors) to train the staff who make inspections. It also enforces regulations, collects information, and generates reports (readily available on the FRA Web page) dealing directly with railroad accidents or safety issues. It also monitors and reports on train accidents and safety-related incidents.

It is worth noting that while the Office of Railroad Safety is responsible for setting and enforcing rail safety policy, it does not conduct the investigations following a rail disaster. That function is performed by the NTSB, an independent agency not part of the Department of Transportation. In the event of a railway accident (collision, derailment, or the release of toxic substances), inspectors and other staff from

the Railroad Safety office participate and assist, but the accident investigation is completely the responsibility of the NTSB, just as it is in the event of a maritime or aviation accident. As part of its task, the NTSB develops and issues a report at the conclusion of the investigation. The reports, which are available on the NTSB Web site, contain a series of appropriate recommendations to all parties, including the FRA but also other involved parties, such as railroad companies or railroad worker unions.

The second major office that is at the heart of FRA operations is the Office of Railroad Policy and Development. The Office of Railroad and Policy Development works directly to improve and maintain railroad operations. Its mission statement defines its operations as developing cohesive goals and policies for maintaining and improving the U.S. freight and passenger rail networks. A large part of its activities is supporting these efforts through managing the financial aspects (loans and grants) of these projects. In addition, the office conducts research and development in rail technology, draws up the rules for the methodologies for rail planning at all levels, and provides technical assistance for all parties (current and future) that will receive grants or loans.

The Federal Railroad Administration (FRA) performed this 2011 crash test in which a locomotive rammed into loaded hopper cars. The FRA is responsible for regulating the rail industry and for rail safety issues, but accidents are investigated by the independent National Transportation Safety Board.

It does this through the efforts of four subordinate organizations: the Office of Program Planning and Administration, the Office of Passenger and Freight Programs, the Office of Research and Development, and the Office of Policy. The Office of Program Planning and Administration is responsible for managing and supporting all efforts of the other three organizations. The Office of Passenger and Freight Programs is the financial branch of the office and manages grants and loans. The Office of Policy develops policies, makes policy recommendations, and also monitors developments throughout the industry. The FRA also supplies support and administers federal grants to Amtrak, which provides passenger rail service.

Northeast Corridor

While passenger service throughout the United States has declined over the past decades, in the stretch between Washington, D.C., and Boston, it is a high-profile operation. In addition to the major passenger service between those cities, the Northeast Corridor (NEC) also includes regional commuter lines, as well as rail lines that radiate out from the main line. In total, passenger service coupled with large freight operations results in traffic that exceeds over 2,000 trains a day. Because of the heavy amount of freight and the significance of the cities on the northeastern coast, the operation, maintenance, and projected improvement of the infrastructure is considered to be a major responsibility of the FRA.

While the refurbishment and continued enhancement of the Northeast Corridor has been an important part of FRA planning and operations, it was given a new urgency as a result of Hurricane Sandy, which struck the East Coast in 2012. In May 2013, DOT Secretary Ray LaHood announced that the FRA would provide (through the Disaster Appropriations Act of 2013) funding in the amount of \$30.2 million. Two-thirds of this amount is to reimburse Amtrak for expenses it incurred in removing debris and water as well as repairs to the infrastructural damage from the hurricane. The remainder of the funding is to be used to repair tunnels into and out of New York City that were damaged by the hurricane.

In April 2013 the FRA released the “NEC FUTURE Preliminary Alternatives” report, which presented 15 alternative plans (from a larger body of proposals) for development on the Northeast Corridor with the goal of meeting what it sees as

transportation needs in 2050. The 15 plans will be reviewed and a subset will be chosen. From that group, specific project(s) will be proposed for implementation.

The 15 plans are organized into four levels, grouped A to D, with A-level projects representing more modest objectives and D-level projects being significantly more ambitious. The first three alternatives are aimed at increasing service and capacity along existing Northeast Corridor main lines, mostly in the form of intercity commuter traffic and some intra-urban services. Level B has four alternatives, each of which is directed toward increasing service along the existing “spine” by decreasing the amount of travel time and increasing the number of trains. The third major set of options (Level C) aims to introduce an expansion of the existing main line with the intent of serving markets not previously served and increasing regional services.

The final level (D) is the most expensive, as it entails the construction of a second spine of Northeast Corridor infrastructure. One of the four proposals under discussion in this group is to construct a parallel line running the entire distance from Washington to Boston. The remaining three proposals call for a second line running parallel to segments of the total line. Analysts have also noted that there are two other options in addition to the 15 discussed in the report. One of these would be to adopt nothing in the way of enhancements; the other would be to adopt all 15 projects.

The criteria for judging the viability of the projects will be based, in part, on an FRA report titled “NEC FUTURE’s Preliminary Purpose and Needs.” These include maintenance to be continued on a level that ensures that existing infrastructure can meet future requirements, improves reliability of service, and the ability to meet passenger demand well into the 21st century. Other objectives identified in the report include environmental targets, improved rail capability in the region to assist economic growth, and reduction in energy use.

High-Speed Rail

High-speed rail has been at least discussed as a national program since the mid-1960s, the same time at which the FRA and the Department of Transportation came into existence. High-speed rail has had its champions, who often cite the Japanese “bullet train” or French high-speed railroads

as a model. The concept, however, has yet to win complete acceptance.

Some controversy exists around this program, as there is opposition to allocating public funds to this by those who are opposed to government subsidies for this type of project. In addition, there are some critics who maintain that funds would be better spent on reopening Amtrak lines that have been closed to cut costs, depriving regions of any access to Amtrak. Other critics have cited Amtrak lines (including those on the West Coast that already exist) that provide excellent service at significantly less than high-speed rail capability and that could benefit from infrastructure improvement.

Within a few months after beginning his first administration, President Barack Obama announced a renewed effort to make high-speed rail travel available to 80 percent of Americans. The objectives, as stated then, were to build new high-speed rail corridors, to upgrade existing intercity passenger rail corridors, and to create the basis for future high-speed rail services. Among the promised benefits, according to the FRA, high-speed rail programs would encourage regional economic growth, increase mobility and options for travelers, and decrease dependence on oil. High-speed rail efforts were incorporated into the American Recovery and Reinvestment Act of 2009. As of 2010, total funding was \$10.1 billion. Thus, high-speed rail has become a priority project within the FRA, at least for the present.

Similar Regulatory Agencies

An organization similar to the FRA is the European Union's European Railway Agency (ERA), which employs 100 people. In existence since 2004, ERA's mandate is to assist innovations to promote European rail competitiveness through compatibility and safety regulations. Another organization that performs a similar function is the Canadian Rail Safety Directorate. In the United Kingdom, the Office of Rail Regulation exists as a section reporting to the secretary of state for transport. It oversees adherence to safety and economic regulations by British railroads. Rail issues in Japan are managed by the Ministry of Transportation. India's Ministry of Railways is responsible for operation of Indian Railways.

Federal Transit Administration

The Federal Transit Administration (FTA) is an agency under the oversight of the U.S. Department of Transportation. The FTA provides assistance to urban transit systems throughout the United States through grant and loan programs that finance both capital expenditures and operating expenses and

ensures that recipient transit agencies are in compliance with federal and programmatic regulations.

While federal funds had occasionally been used to build transit infrastructure or maintain public transportation operations during President Franklin D. Roosevelt's administration (for example, the role of federal funds in building portions of subways in Chicago and New York), federal transportation policy during the post–World War II period focused primarily on building highways and encouraging the use of the private automobile. The Federal Aid Highway Act of 1956, signed by President Dwight Eisenhower, funding the nation's Interstate Highway System, was largely seen by critics as leading to the demise of urban mass transit agencies, causing them to close or reduce available services. As transit ridership declined due to the popularity of the private automobile and the massive federal investment in roads and highways, urban areas began to experience increased levels of traffic congestion, pollution, and physical and social isolation of nondrivers and those too poor to own a vehicle.

1960s

On June 30, 1961, President John F. Kennedy, recognizing the social and environmental implications of existing transportation policy, signed the Omnibus Housing Act, which, among other things, stated that mass transit is “a distinctly urban problem and one of the key factors in shaping community development.” Originally seen as a form of demonstration project to test whether there could be a worthwhile federal role in shaping and funding transit policy at the local metropolitan level, this act created an urban transit assistance program and placed it under the supervision of the U.S. Housing and Home Finance Administration (now known as the U.S. Department of Housing and Urban Development). The 1961 Omnibus Act provided \$25 million for grants and \$50 million for loans for pilot projects in mass transit, largely seen as a way to create transportation options for those too poor, young, old, or disabled to drive private vehicles.

President Kennedy continued to advocate a larger federal role in funding and shaping local transit policy because of its social implications. In 1962, President Kennedy's secretary of commerce and the housing and home finance administrator sent a letter to Congress advocating a “balanced” transportation system—one that did not overemphasize

car ownership to the detriment of public transportation—that could assist communities in land use planning, mitigation of traffic congestion, and provision of mobility options for nondrivers. The letter cited a decades-long cycle of service cuts and fare increases, which reduced the ability of transit agencies to provide services to low-income communities. The letter was seen as a significant lobbying effort to create new and continued programs of grants and loans for transit agencies.

President Kennedy, in a subsequent statement to Congress, said the following:

To conserve and enhance values in existing urban areas is essential. But at least as important are steps to promote economic efficiency and livability in areas of future development. Our national welfare therefore requires the provision of good urban transportation, with the properly balanced use of private vehicles and modern mass transport to help shape as well as serve urban growth.

After President Kennedy's assassination, Congress passed and President Lyndon B. Johnson subsequently signed the Urban Mass Transportation Act of 1964 on July 9, 1964. Originally proposed by President Kennedy, the Urban Mass Transportation Act of 1964 created the Urban Mass Transportation Administration (UMTA), which eventually became the FTA, and encouraged “the planning and establishment of areawide urban mass transportation systems needed for economical and desirable urban development.” By authorizing federal grants and loans for transit infrastructure and services, the act provided sources of additional revenue for the nation's transit agencies. Congress, however, did not authorize expenditures equivalent to President Kennedy's vision, appropriating less than \$150 million per year under the act.

In 1965, 1966, and 1967, various race-related riots occurred in major U.S. cities, including Los Angeles, Detroit, Chicago, and Newark (New Jersey). Occurring in majority–African American neighborhoods, the riots focused attention on the communities' sense of isolation because of inadequate transit availability. In the Los Angeles Watts neighborhood, for example, a bus ride to the County General Hospital took two hours each way; to reach the Youth Employment Training Center required

one hour and 45 minutes in each direction. Los Angeles's burgeoning freeways did little to assist Watts residents, largely too poor to own a private vehicle, with mobility challenges.

The National Advisory Commission on Civil Disorders, more popularly known as the Kerner Commission, was convened by President Johnson to investigate the causes of the riots and highlighted the inadequate transportation systems in many inner-city neighborhoods. Inadequate public transportation, the commission found, created hostility and was one factor precipitating the riots. The Kerner Commission's findings, as well as the perceived success of the grants and loans provided by the UMTA, led to the transfer of the UMTA to the Department of Transportation in 1968 and congressional passage of the Urban Mass Transportation Assistance Act of 1970. The act substantially increased funding of the UMTA—from \$150 million to \$500 million in 1972—and broadened the size and scope of loans and grants available to transit agencies.

The UMTA's *External Operating Manual* of 1970 clarified the goals of federal involvement in transit operations: providing transportation options to nondrivers, mitigating traffic congestion by providing mobility options to drivers, and positively impacting urban land use patterns and furthering environmental protection goals. Specifically, the manual stated, small metropolitan areas (those with less than 250,000 in population in 1970) should focus on enhancing transportation options to individuals lacking access to a private automobile. Mid-sized areas (between 250,000 and 1 million residents) should focus on reduction of traffic congestion. Large metropolitan areas (those with more than 1 million residents) should focus on improving land use and development patterns, presumably through the reduction of suburban sprawl. Thus, transit and transportation agencies across the United States were expected to promulgate the UMTA's goals in their applications for federal funds.

1970s and Beyond

The greater availability of federal funds to local transportation agencies through the Urban Mass Transportation Assistance Act of 1970 caused transportation planning to become a much more complex endeavor in the 1970s. Transit and transportation agencies receiving federal funds were required to collect and report data on a wide range of societal,

The Los Angeles Metro Gold Line light rail train, seen here at the Little Tokyo station on the opening day of its eastside extension on November 15, 2009, brought a new mass transit option to an area of the city that had long been underserved.

economic, and consumption impact metrics. The increased data reporting and collection requirements necessitated an increase in the administrative capacity and professionalism of agencies funded by the UMTA. The escalating complexity of transportation planning also formally linked transportation policy, and by implication the behavior of transportation agencies, with the social, natural, and business-related environment of U.S. cities—a reflection of President Kennedy's influence a decade earlier.

The Surface Transportation Assistance Act of 1982 was one example of the social impact of transportation planning and the role of Congress in determining both the UMTA's and local transit agencies' policies. This act required transit agencies to expand their services to include accessibility for all persons with disabilities; alternate transportation services, operating in the same geographic area and during the same times as general transit services, were required to be made available to anyone unable to use the system and at a comparable fare. While the act greatly expanded the availability of transit services for the disabled, it was an unfunded mandate. However, it specified that transit agencies were not

required to spend more than 3 percent of their operating budget on compliance with the act to avoid an excessive financial impact on transit agencies.

In 1991, Congress, in the Intermodal Surface Transportation Efficiency Act (ISTEA), Title III Federal Transit Act Amendments of 1991, renamed the UMTA the Federal Transit Administration (FTA). Congress and President George H. W. Bush sought a new name for the agency that better reflected its growing responsibilities, including provision of public transportation in rural areas and various transportation programs not technically considered “public.” The act further increased expenditures for the FTA to approximately \$5 billion a year, created new formula and discretionary grants, and established a transit planning and research program.

Programs and Administration

An administrator appointed by the president oversees the FTA and also reports to the secretary of transportation. The administrator oversees the 500 employees of the FTA and an annual budget of \$9 billion. In addition to its headquarters in Washington, D.C., the FTA maintains 10 regional offices in the metropolitan areas of Boston, New York, Philadelphia, Atlanta, Chicago, Fort Worth, Kansas City, Denver, San Francisco, and Seattle.

The FTA maintains two types of grant programs: discretionary and formula. Both types of grants were authorized by the 2005 Safe, Accountable, Flexible, Efficient Transportation Equity Act: A Legacy for Users (SAFETEA-LU). Examples of discretionary grants include Alternatives Analysis, Bus and Bus Facilities, Capital Investment Program, Clean Fuels Grant Program, National Research and Technology Program, Over-the-Road Bus Program, Transit in Parks Program, Public Transportation on Indian Reservations, Transportation Investment Generating Economic Recovery Program, and the Transit Cooperative Research Program. Formula grants administered by the FTA include Fixed Guideway Modernization, Job Access and Reverse Commute Program, Metropolitan and Statewide Planning, New Freedom Program, Rural Transit Assistance Program, Transportation for Elderly Persons and Persons with Disabilities, and Urbanized Area Formula Program. Each of the grants and programs require congressionally appropriated funding.

When a transit agency receives a grant from the FTA (as practically all do), it agrees to follow all federal regulations regarding public transportation and to report data to the FTA on various administrative elements like revenues, funds from other units of government, capital expenditures, operating costs, types of vehicles in use, ridership statistics, number and types of employees, energy usage, and on-time performance. It should be noted that transit agencies receiving federal funds are also required to report data on transit services that they contract out to the private sector.

While the role of the FTA in mitigating traffic congestion, urban air pollution, and suburban sprawl has arguably been mixed, the agency has played a large role in the provision and maintenance of existing transit agencies and infrastructure in the United States. By providing financial support to local agencies, the FTA is also able to oversee the actions and programs undertaken by local transit agencies, ensuring compliance with federal law and administrative constraints. The FTA also provides professional guidance to individual agencies with recommendations on areas including capital investment, transit finances, and transit-oriented development.

Federal Transportation Policy

Federal transportation policy encompasses the plans, programs, and actions taken by the federal government that are concerned with the movement of goods and people. In the United States, transportation policy takes place in an intergovernmental and multisectoral context, with the federal government playing an important role in ensuring coordination and collaboration. The federal government's primary role is to fund transportation infrastructure and regulate interstate and international commerce. Federal transportation policy has been characterized as fragmented and lacking a coherent overall national transportation policy. As the interstate system neared completion, passage of the Intermodal Surface Transportation Efficiency Act of 1991 (ISTEA) shifted federal transportation policy toward a more intermodal approach with greater flexibility for states and localities, marking a new, postinterstate era in federal policy.

Absence of National Transportation Policy

Despite creation of the federal Department of Transportation in 1966, the United States has not had a coherent overall national transportation policy. Transportation policy scholars point to the Transportation Act of 1940 as the first express transportation policy adopted by the federal government, with piecemeal additions and alterations made with each subsequent federal transportation legislation. John Coyle and his colleagues note that federal transportation policy is a composite of different federal legislations, rules, funding programs, and regulatory agencies, with the marked absence of a unified federal transportation policy statement or goal.

This fragmentation partly results from diverse interests and concerns driving federal transportation policy (such as interstate commerce, military preparedness, global competitiveness, and homeland security), which have resulted in multiple goals. The many (sometimes conflicting) policy goals include safe and efficient operations of multiple transportation modes; critical transportation infrastructure provision; regulation of private enterprise performing transportation functions; security of transportation facilities and operations; equitable access to transportation facilities across a

diverse population; and integration of transportation with concerns such as the environment, energy consumption, and economic development. Furthermore, the patchwork of ownership, funding, and operations for different modes of transportation across multiple sectors and levels of government further complicates national transportation policy.

Mode-Specific

Mode-specific policy has contributed to the fragmentation of federal transportation policy. Federal legislation usually considers water transport, rail, highways, air carriers, transit, and pipelines separately. Each mode has developed in a distinctive historical manner, and each has posed unique problems for policy makers and program managers.

While the modal approach is useful for organizing purposes (and the U.S. Department of Transportation is thus organized), it becomes problematic in terms of having a coherent national transportation policy because each mode does (and should) not operate separately from the others. Ports and airports need access to surface transportation for passengers and goods to travel without interruption. Addressing congestion requires that highways, transit, bicycle and pedestrian facilities, and commuter railroads fit together within the transportation network. Yet, pre-1990s federal policy was largely mode-specific and not integrative. More recently, following the passage of ISTEA, federal policy has become more intermodal, emphasizing the integration of various transportation modes into a single system.

Multi-Sectoral

The federal approach to transportation has also been multisectoral, relying on formal and informal public-private partnerships. Historically, the United States has relied on private enterprise for most transportation services, with the federal government furnishing and financing basic infrastructure (for example, roads, bridges, waterways, port facilities, airports) and regulating the private sector. This partnership characterizes air, highway, water, and, to some extent, rail transport. As early as the 1800s, the federal approach to transportation policy involved providing financial support to private transportation companies. First with private canals and then railroads, the government gave public subsidies, mostly as land charters or land grants, to companies to develop transportation facilities and

services expected to benefit the public. Later subsidies included direct federal cash assistance. However, as these private companies became more economically and politically powerful, federal policy took a more regulatory stance, using governmental power to push the private sector toward achieving public goals.

Beginning with the Interstate Commerce Act of 1887, federal regulatory agencies were established for tasks such as setting rates, licensing carriers, maintaining public safety, authorizing routes, and monitoring other permissible activities of private enterprise. However, these regulatory agencies tended to operate in “silos,” isolated from high-level policy leadership, making it difficult to pursue clear and coherent policy goals.

During Franklin D. Roosevelt’s administration, the regulatory approach was expanded to cover virtually all aspects of transportation. Aviation, the merchant marine, coastal shipping, trucking, and intercity bus services were all subject to regulation. While some argue that this regulatory policy has helped stabilize the country’s transportation system, critics say that the decentralized, legalistic regulation approach cannot deal with the complexity of transportation’s societal impacts and has hindered economic efficiency improvements needed to reduce transportation costs’ importance as a factor in production and personal travel. Beginning in the 1970s, the federal government’s regulatory stance softened, as evidenced by deregulation of the railroad, trucking, and aviation industries.

Intergovernmental

The federal government’s financing role is most dominant for surface transportation such as highways/roads and transit. States and localities have been the major implementers of federal transportation policy with federal financial assistance, owning and operating transportation facilities and playing key roles in transportation planning.

The automobile revolution raised the need to improve and expand the country’s road network. To create this national network, the federal government provided grants-in-aid to states and localities to financially support their capital investments. States and localities remained responsible for maintenance and ownership. This intergovernmental approach, cemented during the interstate-building era and institutionalized through the

federal-aid highway program, shaped contemporary federal policy.

Whereas the intergovernmental nature of the transportation program had been primarily federal–state, ISTEA introduced a federal–state–local transportation program by strengthening the role of metropolitan interests in transportation planning. It significantly enhanced state and local government officials’ power in surface transportation project selection. While many have argued that ISTEA represented a shift in attention from primarily one mode—highways—to other modes such as transit, others have suggested that it reflected a shift away from a federal emphasis toward the local and regional dimensions of transportation policy.

Conclusion

Despite fragmentation and challenges to coordination and collaboration, federal transportation policy has been a key player in nation-building efforts. Over the last 100 years, the federal role has shifted from the emphasis on providing rural post roads for getting produce to market, to connecting the nation’s centers of population, to addressing mobility and congestion problems, to promoting global competitiveness. Along this historical path, there have been varying emphases on defense and military preparedness, urban renewal, disaster relief, social equity, and homeland security.

ISTEA and subsequent federal legislation shifted federal transportation policy away from the broad focus on connectivity toward a set of goals for enhancing mobility, access, safety, environmental protection, and quality of life. Yet no clear organizing principle has replaced the Interstate Highway System as the rationale for federal policy. In addition, although the federal influence over transportation policy remains significant, the recent federal legislation (Moving Ahead for Progress in the 21st Century, or MAP-21) continues the emphasis (begun by ISTEA) of increasing the decision-making authority of state and local governments.

Ferries

Ferries are marine vessels that transport passengers, automobiles, freight, or some combination of the three over a river, lake, or other body of water. Ferries have traditionally provided a vital transportation link for people living near waterways. As early as the 17th century, ferry service was in operation in the Massachusetts Bay Colony. Ferry service was particularly important before advances in engineering made possible construction of permanent bridges and tunnels across bodies of water, and later it was used in many rural areas and in some urban areas to move commuters, business travelers, and tourists across waterways.

By the end of the 20th century, 134 million passengers were using ferries in the United States. Although the number of ferry passengers declined in the 21st century, ferries continued to be an important transportation service in the United States, particularly in coastal urban regions. In 2012, the National Census of Ferry Operators reported that 233 ferry operators in 36 states and two U.S. territories operated a fleet of almost 640 active vessels. Urban planners and security experts agree that ferries can continue to play a significant role in the nation's transportation system for the foreseeable future.

From Canoes to Fast Ferries

The first ferries in the United States were canoes. In May 1631, the General Court of the Massachusetts Bay Colony granted the right to operate a ferry between Winnisimmet and Boston. A rower for a few pennies transported a single passenger, allowing the passenger's horse to swim behind the canoe.

The ferry was a success. In 1712, legislation required a third boat be added to the fleet, and in 1749, additional legislation mandated that four boats operate for the transportation of passengers. Two of the boats were required to have sails in addition to oars; it also required two sober and able-bodied men to operate the boats and set operation hours. The Winnisimmet Ferry operated continuously until 1917. The Rocky Hill Ferry holds the record for the nation's oldest continuously operating ferry. From 1655 until its closing in 2011, the ferry transported passengers across the Connecticut River, privately operated for the first 260 years and operated by the state of Connecticut from 1915 until its closing.

The busiest ferry system in the United States traces its beginnings back to the 18th century, when it was run by private companies. It was not until 1905 that the City of New York took control of the Staten Island Ferry system. The first year of operation under the city's authority saw five new coal-burning steam ferries launched, each named for a borough of New York, and a nickel allowed a passenger to ride aboard one of them. In 1964, the year the Verrazano-Narrows Bridge linking Staten Island and Manhattan opened, 27.5 million passengers crossed New York Harbor on the Staten Island Ferry. The following year, the number had dropped by 5.5 million. In 2012, total ferry ridership was over 22 million. Another estimated 18 million passengers use private ferry operations.

The Staten Island Ferry may carry the most passengers, but Washington State holds the distinction of having the largest ferry system in the nation. Beginning in 1852 when the first boats of the famed Mosquito Fleet, so named because there were so many of them, filled the waters of Puget Sound, ferries have carried people and goods back and forth across the Sound. From those early days through the early 20th century, ferries were the major mode of transportation in a region where roads were poor where they existed at all.

So important were the ferries to Washingtonians that when finances forced the Puget Sound Navigation Company to tie up its boats after World War II, the state purchased most of the company's assets for \$5 million, and in 1951 the ferry system began operating under the authority of a newly created Washington Toll Bridge Authority, now known as Washington State Ferries (WSF). In the first year of operation as a state-operated system, approximately

The Jumbo Mark II Class ferry Wenatchee crosses Washington State's Puget Sound on a Seattle–Bainbridge Island route in 2007. The ferry can hold up to 2,500 people and over 200 cars at one time. Washington State has the largest ferry system in the United States. In 2012, the Washington State Ferries Authority carried more than 22 million passengers and 10 million vehicles on its 22 ferries.

4 million passengers rode the ferries. In 2012, WSF transported more than 22 million passengers and more than 10 million vehicles on 22 ferries. The system serves eight counties in Washington State and the province of British Columbia in Canada using 10 routes and 20 terminals.

In addition to Washington and New York, California, Louisiana, Massachusetts, New Jersey, North Carolina, Ohio, Texas, and Virginia all have ferry systems that typically carry over 1 million passengers annually. Hundreds of other ferry services, public and private, provide important transportation links in communities across the nation.

The upsurge in interest in ferries during the latter half of the 20th century was in part due to high-speed ferries. A 1999 Maritime Administration study reported that fast ferry ridership grew 6.8 percent per year from 1993 to 1997, even though only about 15 percent of 1,206 passenger ferries in the United States in 1997 were fast ferries. The catamaran, a twin-hulled vessel that offers speed, stability, and space, is the most common choice of fast

passenger ferry operators. With about one-third of U. S. ferries ready for replacement, the study predicted an increase in the number of fast ferries. Although the number did increase, the United States has been less eager than other parts of the world to utilize fast ferries, but growing traffic congestion and environmental concerns lead some experts to predict that will change.

Increased federal funding adds to the probability of more fast ferries. The Moving Ahead for Progress in the 21st Century Act (MAP-21), signed into law by President Barack Obama on July 6, 2012, extended the existing Ferry Boat Program, which had provided more than \$500 million to improve America's ferry boats and terminals in its 20-year history. New funding under MAP-21 brought the 2013 total to about \$64 million.

The Advantages of Ferries

Ferry services offer a less costly alternative to bridge and tunnel construction, a particular concern in urban areas with budgets stretched thin.

For example, the cost for the New Mississippi River Bridge connecting downtown St. Louis with southwestern Illinois was an estimated \$667 million, less than half of the original plan with a projected cost in excess of \$1 billion. In contrast, Washington State's *MV Chetzemoka*, pound for pound the most expensive ferry ever built in the United States at the time of its construction in 2010, cost \$80.1 million. Ferries can also relieve the morass created by securing rights-of-way for bridges, tunnels, and highways. Ferries that are part of urban transit systems are eligible for federal grants, just as highways and bridges are.

Traffic congestion, a major concern in urban areas, is often greatest at bridges and tunnels. Ferries provide an alternative to the transit buses and automobiles in such cases and generally reduce passenger work-trip times. Ferries are also a crucial element in urban security because they can be used to evacuate citizens and to bring in supplies and emergency or military personnel after land-side emergencies.

The best-known example of such use occurred after the terrorist attack in New York on September 11, 2001. On that day between 300,000 and 500,000 people, according to varying sources, were evacuated from Manhattan by water. But ferries had proven their effectiveness for evacuation earlier when they were used to move citizens out of the San Francisco Bay Area after the 1989 Loma Prieta earthquake. Operators of the free Galveston–Port Bolivar ferry consider preparedness for evacuation in the event of a hurricane one of their major responsibilities.

Environmental impacts of ferries include not only the emissions concerns shared with land vehicles but also wake wash, water discharges, and noise pollution. It is fair to say that some proponents have overstated the environmental advantages offered by ferries. Diesel-powered ferries without emissions controls produce more nitrogen oxides but less carbon monoxide per passenger trip than does a car. Environmental activists in the San Francisco Bay Area and in New York have protested ferry systems that failed to fulfill their claims of significantly reducing air pollution, and the Hawai'i State Supreme Court effectively stopped the operation of that state's Superferry in 2009 when it struck down an act passed by the legislature that exempted the ferry's operator, Hawai'i Superferry, Inc., from

carrying out an environmental impact study. But the consensus is that when proper technology is used, ferry systems sometimes decrease emissions and almost certainly will not add to the existing air pollution load. Wake wash, a primary environmental issue with ferries, is manageable with proper implementation and oversight.

Concern about safety has increased with the expansion of ferry services, with vessel instability and insufficient fire protection being paramount. Ferry accidents garner headlines and raise public concerns, but ferries in the United States have an enviable safety record. From 2000 to 2010 the national average of fatalities due to ferry vessel operations was fewer than two fatalities per year.

According to the National Census of Ferry Operators, ferries in the United States provide commuter services in major metropolitan areas on both coasts, offer an essential intercity transportation link between coastal Alaska communities and the lower 48 states, and link roadways and communities separated by various bodies of water. The role of ferries in the U.S. transportation system is a vital one that seems likely to increase in importance.

Fiscal Politics

Most of politics is about money and most of the rest is about jobs. Money has been described as the “mother’s milk of politics,” or, as one definition of politics puts it, politics is about who gets what, when, and how. Transportation fiscal politics is about who, what, when, and where money for transportation needs and projects will be spent.

Many political supporters of candidates and political parties are into politics for the money. That is, they support a candidate in order to gain jobs, contracts, or other interests. Historically, in the United States, the spoils system grew greatly under President Andrew Jackson. It peaked with the assassination of President James A. Garfield by a disgruntled federal office seeker. Thereafter the civil service reduced the number of political appointees. However, in both federal and state governments, many jobs and appointed offices remained for supporters.

U.S. Transportation Funding History

Since the beginning of the republic the Congress has authorized many billions of dollars for transportation needs. Early in its history, the Corps of Engineers was paid to clear snags from the rivers that were used as major transportation arteries. Canal building was financed by a combination of private and public monies. All too often the complaints about wasting public money on canals in the service of private interests was based in fact, as friends were rewarded with contracts that they fulfilled poorly, or bad decisions were made for partisan reasons. The large stone bridge in the Erie Canal, for example, did not last long because porous local sandstone was used against the advice of engineers.

Many railroads were financed by a checkerboard pattern of land grants. The federal government moved alternating square miles of land on either side of the new railroad tracks from public domain into the hands of the railroad company building the tracks in order to finance the line. The government then sold its remaining share of land in order to promote development.

Many transportation projects were opportunities for boondoggles that wasted money on bridges to nowhere or canals or roads that were not used enough to repay their costs in terms of economic benefits. Transportation projects have often been sources of pork barrel politics as legislators, whether

state or federal, sought to bring to their home district money that would be spent on roads, bridges, or other transportation projects, whether needed or not. The politics of pork barrel projects is usually “log rolling” for votes in which legislators or members of Congress cooperate to vote for each other’s spending desires without regard to the public’s interests. The money then spent in the home district is viewed as a sign of political success. Politicians who fail to get pork barrel projects do not last long in office.

The advent of automobiles soon led to the adoption of appropriations for the building of federal highways. The Federal Aid Road Act of 1916 (Bankhead-Shackleford Act) set in place a pattern of federal project grants following a matching funding formula. The road standards were to be set by the American Association of State Highway and Transportation Officials (AASHTO). The bill was signed by President Woodrow Wilson, who was an advocate of good roads as a stimulus to the development of the country.

The funding required that the roads be open to the public for use free of charge. Rural road-building plans of the states were to be submitted to the secretary of agriculture for approval before the funds were spent. Consequently, farmers were interested in good farm-to-market roads and in Rural Free Delivery by the Postal Service. The Supreme Court’s decision that the commerce clause (Article I, Section 8) permitted Congress to spend money on interstate roads aided the politics of those seeking government spending for roads. In 1917 it became necessary for every state to have its own highway department in order to administer road-building money.

The Federal Aid Highway Act of 1921 was adopted in order to develop the immense national road system through the Federal Aid Road Program. Programs were administered by a growing number of agencies, such as the Office of Road Inquiry, Office of Public Roads, and the Bureau of Public Roads. These were included in 1966 in the Federal Highway Administration (FHWA), which is a division of the U.S. Department of Transportation.

Interest Groups and Funding

Competing for roads for transportation dollars are canals, river barges, harbors for oceanic shipping, airports, and public transportation systems of buses and railroads. Every form of transportation serves

some set of interests. These interests may be individuals who want transportation to be available and affordable; various interest groups, including environmentalists, bicyclists, labor unions seeking jobs on public projects, business interests seeking contracts for road work, or other associated benefits; politicians; and even government agencies that will administer the money. However, the supply of money is finite and the transportation interests are extensively varied and often competitive. Barges, railroads, and trucking firms compete as freight haulers. They also compete politically by supporting allied groups or business interests in order to secure funding.

Fiscal policies are used to tax and spend for public purposes. Taxation and fees are used to pay for and promote public interests. Spending is allocated to achieve specific policy goals. The political issues between groups competing for transportation subsidies or appropriations involve which kind of tax is levied, who pays it, and who will spend the money. For example, federal and state gasoline taxes are used to pay for highways. The rate of taxation is uniform for the federal tax across the whole of the United States, but tax on fuels varies from state to state as each is free to collect according to its specific needs. Regardless, the tax affects the cost of doing business for taxicabs, truckers, bus companies, and people whose work involves significant amounts of driving. The fuel taxes are used to pay for highways with specific sums allocated to highway contractors.

Every state has a highway department that is organized to reflect the politics of that state. In some the representatives on the highway department board are appointed by the governor and the legislature by congressional district. The goal is to facilitate the politics of the highway funds. The exchange of political support for the various parties is crucial for success but also a source of conflict at times with the public interest, as private interests may be more successful in gaining the support of politicians eager for political support at election time.

Some states follow a pay-as-you-go fiscal policy, which keeps borrowing limited. Other states have been open to borrowing for transportation projects and are practicing an expansionist fiscal policy.

The “Highway Lobby”

Building and maintaining road systems requires funding an ongoing series of construction projects.

Tremendous sums are expended annually by local, state, and federal governments to fund road builders. In the United States almost all roads are built by private companies that are funded by public monies. As a consequence, the competition to get the contracts to build or repair roads is intense. Lobbyists are those who seek to influence government agents, whether from legislative or executive branches of government, to build or to choose their clients.

The “highway lobby” (also known as the “road gang”) is a collection of automobile and truck manufacturers, tire makers, auto parts companies, trucking companies, oil producers and distributors, paving companies, allied companies and their trade associations, and two major lobbying organizations. Allied companies would be those like Dow Chemical, which manufactures automobile and truck cleaning supplies. The highway lobby has been able to dominate ground transportation since the beginning of the 1930s and the great expansion of the highway system.

Funds for the federal highways, both interstates and federal highways, have come from the 1956 Highway Revenue Act, which established the Highway Trust Fund. Prior to the establishment of the Highway Trust Fund financing for federal roads came from the General Fund of the U.S. Treasury. The monies for the Highway Trust Fund first came from a federal tax on gasoline sales, and the supplemental funds could be added from the General Fund of the U.S. Treasury. Since 1956, when the gasoline tax was 3 cents per gallon, the tax has been increased to 9 cents under the Surface Transportation Assistance Act (1982), and then to 14 cents per gallon by the Omnibus Budget Reconciliation Act of 1990. The Omnibus Budget Reconciliation Act of 1993 raised the tax to 18.4 cents per gallon, but all of the money went for deficit reduction and not into the Highway Trust Fund.

The Taxpayer Relief Act of 1997 redirected the 18.4-cent tax to the Trust Fund. Funding was allocated for six-year periods. Currently the Trust Fund is inadequate to meet the costs for highway maintenance and new construction. Tax receipts in the Trust Fund have recently been declining as the use of hybrid and other fuel saving vehicles are used on the nation’s roads. One proposed solution now being tested is the installation of a mileage meter, which would record the miles driven and then

charge drivers in accordance with their mileage. This “user fee” would be a regressive tax and would generate large sums for the Trust Fund.

The leading lobbyist organizations for the Highway Lobby are the American Highway Users Alliance and the American Road and Transportation Builders Association (ARTBA). The American Highway Users Alliance (AHUA) was founded in 1932 by General Motors and other organizations. It was merged with the Automobile Safety Foundation and with the Auto Industries Highway Safety Committee in 1970. It is a nonprofit interest group representing the automobile and road construction industries that publishes research on highway construction, safety, and funding. It lobbies on issues involving highway funding, construction, and safety, and is an advocate for the position that all gasoline taxes should be used for road construction alone. Other interests have sought to divert money from the Highway Trust Fund to other projects, including railway transportation and budget deficit reductions.

The AHUA claims to have been a successful advocate for road construction by the federal government since the 1930s. Its reasons for increasing highway construction have changed over the years. With climate change, oil prices and congestion being discussed as major public concerns, the AHUA advocates increasing highway construction in order to reduce greenhouse gases and improve the economics and safety of ground transportation.

ARTBA is a lobbying organization founded in 1902 and based in Washington, D.C. It is an advocate for road construction with over 5,000 members. Its members study ground transportation infrastructure needs and then advocate for construction funding for projects that will meet these needs.

Opposition to the highway lobby grew significantly after activists were successful in preventing supersonic jet liners from landing and taking off at airports in the United States. Joining with environmentalists and advocates for alternate forms of transportation, especially rail transportation, this opposition formed the Highway Action Coalition. Since the 1970s various groups opposed to the highway lobby have been able to block projects or to divert funds from the Highway Trust Fund to rail projects.

FreedomCAR and Vehicle Technologies Program

The FreedomCAR and Vehicle Technologies (FCVT) Program is a research initiative between the U.S. government and the nation’s automotive and energy industries. It was initiated in 2002 as a successor to the Partnership for a New Generation of Vehicles (PNGV) program, which was a partnership between the U.S. Department of Energy (DOE) and the U.S. Council for Automotive Research (USCAR), made up of DaimlerChrysler Corporation, Ford Motor Company, and General Motors Corporation. The same players formed FreedomCAR—with CAR standing for Cooperative Automotive Research—to further develop technologies that would reduce fuel dependence and engine emissions in U.S. passenger vehicles and light trucks.

In September 2003, the program expanded to address issues related to fuel infrastructure by adding five new members representing key participants in the U.S. energy industry: BP America, Chevron Corporation, ConocoPhillips, ExxonMobil Corporation, and Shell Hydrogen (U.S.). The expanded initiative was renamed the FreedomCAR and Fuel Partnership. Two electric utility companies, DTE Energy in Detroit and Southern California

Edison, joined the partnership in 2008 to help with FreedomCAR's work related to interface and infrastructure issues involving electric vehicle technologies. All the members work together to share resources and devise options for underlying technologies and processes designed to support the initiative's target goals.

The FreedomCAR and Fuel Partnership is focused in the short term on supporting technological research and development of battery-electric vehicles (BEVs) and plug-in hybrid electric vehicles (PHEVs). Its longer term strategic goal is the development of technologies for hydrogen-powered fuel cell vehicles that are not dependent on petroleum and do not generate harmful emissions or greenhouse gases. Like its predecessor, the new partnership seeks to achieve its technology goals while maintaining desired automotive attributes for consumer comfort and mobility.

The partnership's approach involves early focus on more fuel-efficient internal combustion engines and hybrid electric vehicles, as well as the potential use of all-electric vehicles and biofueled internal combustion engines. The group aims ultimately to develop an infrastructure for supplying hydrogen fuel for fuel cell powered vehicles. To address the technical challenges associated with the planned research and development pathway, the initiative has established quantitative technology and cost targets through 2015 in eight areas. The technology targets hone in on these areas: basic combustion and emission control for internal combustion engines, fuel cell power systems, fuel cells, hydrogen storage systems, energy storage systems for hybrid vehicles, hydrogen production and delivery systems, electric propulsion systems, and materials for lightweight vehicles.

Structure of the Partnership

The FreedomCAR and Fuel Partnership comprises several oversight groups and technical teams. The Executive Steering Group is responsible for the program's governance and includes the DOE assistant secretary for the Office of Energy Efficiency and Renewable Energy (EERE) and a vice-president-level executive from each of the partnership's member companies. The FreedomCAR Operations Group is driven by DOE program managers and USCAR company directors. It is charged with directing the partnership's technical teams

and prioritizing its research issues. The Fuel Operations Group comprises DOE program managers and directors of the member energy companies and has oversight of the FreedomCAR technical fuel teams. The Utility Operations Group was added to the organization in 2009, led by DTE Energy and Southern California Edison, to address coordination between electric-based vehicle technology and electric utility infrastructure.

The organization is also divided into operational technical teams that establish specific technical and cost targets and direct research and development in the areas of appropriate candidate subsystems. Each team creates research and development plans and roadmaps, reviews research results, and evaluates technical progress toward meeting stated research goals. The majority of the technical teams are centered on a designated technology, such as fuel cells or electric grid interaction, but some work collaboratively across all technical teams to ensure consistency. Examples of interdisciplinary teams include those working on codes and standards and systems analysis of vehicles. Each technical team generally includes DOE technology development managers as well as scientists and engineers with technology-specific expertise from the USCAR member companies, energy and utility partners, and national laboratories. Within the DOE, primary responsibility for the FreedomCAR and Fuel Partnership falls under two EERE offices: Vehicle Technologies and Fuel Cell Technologies.

Technical Areas of Research

The FreedomCAR and Fuel Partnership continues to research and develop technologies aimed at delivering fuel-independent, low-emission vehicles that offer freedom of both choice and mobility for U.S. consumers.

The partnership is investigating all aspects of advanced internal combustion engine operations and emission controls. Efficiency enhancements have been achieved and additional research is being conducted in the areas of combustion, emission, and kinetics of fuel derived from biomass. Specifically, work is aimed at understanding the underlying changes that occur in ignition and emission-formation processes when different compounds found in biofuels are used in the engine.

Fuel cell technology is a key area of the partnership's research because, along with the hydrogen

fuel they would consume, fuel cells offer the promise of zero emissions, high efficiency, and smooth, quiet operation associated with an electric propulsion system. The research and development efforts in this area have led to significant progress regarding performance increases and cost declines, but nothing as of early 2013 that was ready to compete directly with conventional systems.

Onboard hydrogen storage as an enabler for fuel cell powered vehicles is another key target. The goal is to cultivate the development and demonstration of commercially viable hydrogen storage technologies for both transportation and stationary applications. An explicit objective of the program is to achieve a vehicle driving range of more than 300 miles between refueling stops while at the same time meeting vehicle packaging, weight, cost, and performance requirements. The onboard hydrogen storage research also includes life cycle issues, energy efficiencies, safety, and environmental impact.

The partnership is looking into improving electrochemical energy storage technologies as well, especially high-energy batteries and ultracapacitors. Significant improvement in their performance could result in greater electrification to power BEVs and PHEVs. Lithium-ion battery technologies have been a particular area of promise for achieving high power, energy, and other performance requirements for electric vehicles at lower costs than other battery systems.

In the area of electric propulsion and electrical systems, the partnership has focused on key pre-competitive technical targets, such as packaging, cooling, materials, and devices, which can be designed to help achieve long-term reductions in volume, weight, and cost. Similar goals are set for structural materials, where some progress has been demonstrated in the area of magnesium powertrain components.

Teams under the fuel cell technologies office are addressing fuel pathway integration, hydrogen production, and hydrogen delivery issues to identify needs and gaps regarding short- and long-term production and distribution of hydrogen for transportation purposes. Biofuels distribution is also on the partnership's research agenda.

Freight Handling

Ever since Roman times, trade flows have relied on the development of new transport infrastructures. Famous routes have included the Mare Nostrum or the Great East Road with its jade and silk routes, and later, those connecting the medieval fairs of Flanders, Lombardia, the Hanse, and the Ile-de-France region. The revival of the Mediterranean basin and the discovery of the New World further accelerated those trends. While these developments have strongly rested upon the work of those in charge of transport operations, the workers who handle and shift the freight to be stocked or delivered have played an equally important role. Ship suppliers, dockworkers, dock laborers, and longshoremen in the United States; stevedores in Great Britain; wharfies in Australia; timber rafters on the Lumber River in North Carolina; permanent packers and casual meat porters at the Paris Central Food Market; hucksters, street sellers, four-season merchants, and rag-and-bone men in the United Kingdom; junkmen in the United States; and warehouse

assistants all over the industrialized world—all have been (or still are) the backbone of the freight chain.

Throughout the 19th and 20th centuries, the emergence of major infrastructures around the globe—for example, the Pacific and Missouri Pacific Railroads, the St. Louis–San Francisco Railway, the Suez and Panama Canals, the Trans-Siberian, the Jingbao Railway, the U.S. interstate routes and Golden Gate Bridge, the railway connecting Zouerate to Nouadhibou in Mauritania, the Mont Blanc, Seikan, and Channel Tunnels, or the Pearl Bridge in Japan—was closely followed by the expansion and diversification of transport modes.

Until the invention of the shipping container by Malcolm MacLean in 1956, the transfer of goods required some significant physical activity. When the crate containing the goods was separated from the truck trailer frame, and when merchant ships were tailored to transport the freight, packaging became standardized, which led to the development of intermodal transport and the industrialization of port operations.

Following this short historical reminder, this article now turns to the numerous tasks performed by freight agents in the haulage and logistics sectors. This is followed by a focus on the organization of handling activities with especial attention to the constraints and enabling factors, including details about the tools and equipment commonly used by agents. The final section on the intensification of work and its consequences ends with an attempt to briefly outline future perspectives.

Occupations

In the United States, according to the Bureau of Labor Statistics, freight handling falls within the transportation and material moving occupations sector, which includes two categories: (1) hand laborers and material movers (3,315,400 in 2010) and (2) material-moving machine operators, including construction and transportation (669,000 in 2010). Even though they are not recorded as such, delivery truck drivers and driver/sales workers (1,262,600 in 2010), together with heavy and tractor-trailer truck drivers (1,604,800 in 2010) also undertake freight-handling duties as part of their work. This group of workers also includes maintenance technicians, handling engineers, and logistics-related staff (logistics coordinators, order assistants, etc.) in charge of finalizing the distribution of freight.

Freight handling includes the loading and unloading of vehicles in a wide range of settings: transportation scheduled and air courier terminals; ports; platforms supported by e-commerce (trucking and courier, parcel delivery services); combined railroad, waterways-road, or multimodal water-road-rail platforms; and product supply and household delivery services.

In all these modes, workers handle manufactured goods or bulk materials (raw food such as grains or building materials such as gravel, sand, and wood, and even garbage in some instances). In the case of bulk handling, goods are either solid or liquid and remain unpackaged or undocked. Manufactured products may be packaged or placed on pallets or in containers. “Heavy parcels” (engines, turbines, rockets, etc.), which constitute exceptional freight, are kept separate.

Operations and Handling

Depending on the platform from which they handle the freight, agents may undertake a variety of operations, such as container stuffing, stowing, loading, unloading, transshipment, stacking, degrouping (that is, container emptying), and preparing the distribution. Even if the containers require some checks, as well as cleaning and maintenance, many intermediary tasks have disappeared as freight from different shippers is now generally combined in one single shipment.

Freight handling may occur either at the beginning or the end of the supply chain, or between several transport modes or shuttles. However, it always occurs when the load reaches its breaking point in the transport chain. Agents working at the terminals of major exchange routes tend to handle mainly bulk or containers, whereas those working on end-of-circuit platforms are most likely to handle parcels. In any case, agents’ performance is measured against the flow of traffic in these nodes of the transport network.

Their activity is constrained by two factors. First, the volumes to handle vary significantly over time, and unless the means of production are adjusted, the operations may cease to be profitable. These operations are already under strain because they require significant investments (particularly on terminals) and also because they are subjected to important locational competition. Moreover, the operational planning prepared on the day preceding arrivals does

not make it possible to deal with all the events that may jeopardize the smooth running of the system.

Second, next to dysfunctions intrinsic to operations, handling is exposed to the same hazards as the transport modes (density of traffic, mechanical problems, deteriorated infrastructures, bad weather conditions, etc.). The agents' performance is therefore also affected by external factors. A particular challenge, then, is to ensure that the site does not get overloaded and that waiting times are kept to a minimum. The production system thus crucially needs to be reactive and adaptable.

The system's ability to adjust mainly depends on the means of production and on its labor force. Before the container revolution, the organization of production used to rely on temporary piece workers (particularly for unskilled jobs) so as to adjust capacity to demand. Hence, to be hired, dockworkers, longshoremen, stevedores, and wharfies had to wait for the ships to arrive. Even today, many handling operators employed on parcel services platforms or in warehouses are hired a few days before or on the eve of the freight's being delivered. When specialist skills are required (that is, for reach stacker drivers, crane operators, or container crane operators), it is not always possible to rely on temporary staff. In case of late arrivals or unusually high freight volumes, permanent agents may be called upon unexpectedly. Agents' ability to use multiple skills allows the system to adjust. In many inland ports, agents can be assigned to different positions (container crane, reach stacker), tasks (freight handling, container cleaning, checks and approvals), or sites for a day, half a day or even a few hours. The agent may also be assigned to a different time slot than his usual one.

Thanks to multitasking, the task of supervising production can be shared among foremen and frontline operators (team or quay managers). This arrangement is vital given that the dynamics of the situation result from a combination of what happens on the site and in the local vicinity, the temporalities of the various processes (shipping mode and handling operations), and the vagaries of the transport chain. Inversely, foremen may occasionally carry out handling operations to relieve frontline operators of a heavy workload.

The tools used for handling are determined by the environment, the goods, and their packaging. Agents are specialized accordingly. On container or

bulk terminals, crane operators may be in charge of steering fixed or mobile container cranes or gantries under the foreman's supervision through a system of shared information. Forklift truck operators use mobile quayside container cranes, straddle carriers to pick up the containers, or reach stackers to lift them up. Driving or moving on the site without causing undue risks for people or goods requires a skillful mastery of the equipment, which can only be acquired after a long training period.

Delivery

If we now turn to parcel delivery services, depending on the level of package standardization, two types of platforms can be distinguished: nonuniform and standardized.

Unless processes are standardized, agents have to handle a great variety of parcels in terms of length, volume, and weight. In addition, there may be varying levels of fragility, value, or danger. Since incoming goods are rarely grouped, agents are required to prepare pallets. Inversely, they may be asked to "de-palletize" the freight when the existing pallet has become deteriorated. Thus, there is still a certain degree of manual handling and stacking. Handling agents commonly use rolling equipment such as sack trucks or dollies. But most of the time, they use pallet trucks for horizontal handling on more important distances between different spans. Forklift and stacking trucks allow both horizontal and vertical handling. The second type of parcel service concerns express delivery, in which parcels are standardized. A conveyor belt reduces the need for agents to constantly move around. In some cases, it may lead to task automation (hence to job losses).

Even if there is still much paperwork to deal with (loading sheets, train composition, orders), the transfer of information has undergone a significant evolution with the introduction of information systems. Unless the goods are recorded upon their receipt, the risk of their going astray is high. The recording is done through a scan when the systems of each agent (loader, carrier, and handling agent) are compatible. One of the most noteworthy changes is the use of voice picking at the end of the supply chain, which allows the warehouse order assistants to receive the instructions from the information system itself. As his approvals go through, the agent obtains the code, the quantity, and the localization of the goods to be prepared on his cart. Through a screen installed in

his reach stacker, the operator receives similar information about the containers.

Risks

The global economy has led to an increasing use of just-in-time and intermodal operations, thus multiplying ruptures in the supply chain. This prevailing trend in the production system reduces time adjustment margins in case of unexpected events. Today, information systems increasingly facilitate the identification and traceability of goods. The capacity to control the system is much higher, jobs require much more sophisticated skills, and recovery times are lower. The combination of all these factors leads to an intensification of work.

For all the modes, handling the vehicles immediately upon their arrival or seeking to reduce waiting times is particularly important when the cost of immobility is high, as is the case for cargo ships. Consequently, agents have to work on irregular or staggered shifts. Their work also entails significant physical efforts (recurring heavy workloads, painful postures) and exposure to a range of environmental factors (for example, important heat variations, bad weather conditions when working outside, engine noises and vibrations, and toxic products, particularly when handling bulk material). The prolonged exposure to these harmful factors leads to many long-term health risks such as musculoskeletal disorders and occupational diseases such as cancers.

In addition to these long-term health risks, significant accidents can occur on the platforms used for handling activity. This is because there are conflicts over the usage and sharing of space. With the exception of automated chains, the platforms are characterized by numerous vehicle movements. Even if most of the time there are traffic schedules, the vehicles can cross over or encounter pedestrians. Visibility is limited because of how space is laid out, with merchandise being piled up and hiding machinery or agents.

Vehicles and machinery often collide or fall over during checks or installation of twistlocks. Moreover, slips are frequent because of leaks. In the case of hand operations, the mishandling of merchandise can cause sprains. The portage or falling over of parcels can cause lower back injuries and vertebral compression fractures. More generally speaking, objects falling down or spatters can sometimes lead to work incapacity.

Military personnel transfer cargo from a support ship to the USS Dwight D. Eisenhower aircraft carrier in the Persian Gulf, April 5, 2007. Hands-on cargo handling like this has a high potential for injury and long-term health risks.

Automation

Despite the slowdown due to the worldwide economic crisis that started in 2008, the global traffic of containers keeps on growing. Private operators are thus tempted to automate a great part of their handling operations so as to increase the processing capacity of operations outside normal business hours. Irrespective of the mode and container being used, new automatic handling systems (automated stacking cranes, automated guided vehicles, automatic postal parcel turning machines) have appeared. These systems are adapted to standardized operations both with regard to merchandise (parcels or containers) and signage (that is, shared

data sheets and information systems). Yet they require human intervention whenever the situation differs from what is expected because of problems such as failing or erroneous information, damaged parcels, twistlock deficiencies, or overloads, as is often the case in transport systems.

Such contingencies are unlikely to disappear in the foreseeable future, notably because of the growing significance of e-commerce. Consequently, attempting to supersede the human factor through machinery would be highly damaging for freight handling and hence for the transport system at large. The interaction between human agents and their environment will thus remain a subject of scrutiny for academics and practitioners alike.

domains. The “tariffs,” fees, and/or taxes were added to the price of the goods. In this sense, a tariff is a tax. Tariffs were used in the United States during most of the 19th century in order to protect American industries from foreign competition and to finance the federal government.

Transporting goods is expensive so transporters developed systems for pricing the cost of shipping cargo. Their charges for transporting would be the tariff or the freight rate on land or the freight on board a ship. Whether by land or by sea, the tariff or freight rates depended upon the kind of cargo and its destination. Shippers priced the cost of carrying the cargo or freight in terms of its type, its weight, its distance to its delivery destination, any transit services, and other factors. For example, the tariff or freight rate for shipping animals would include the cost of passage on a train or a ship as well as the cost of keeping the livestock supplied during a voyage. In many times and places, shippers were able to set their own freight rates. The table of charges set by a railroad, bus line, trucking line, airline, barge operator, or oceanic shipper would be its bill or cost or charge or tariff.

In modern times, freight rates have continued to reflect the destination as well as the type of transportation (train, truck, ship, bus, aircraft) because the costs vary, often in relation to the speed of delivery. So shipping by air is generally more expensive but worth the cost for perishable goods or for timely delivery.

In competitive shipping markets freight rates are set competitively by different companies. In competitive markets, entry to providing shipping is usually very open to newcomers. However, in many modern markets governments have intervened for political reasons. In these regulated market situations, the freight rates are set by government agencies in order to protect politically active interests from “excessive” charges. However, it has been common for the regulated transportation market to then be closed, with a government-controlled monopoly or oligopoly providing shipping. The closed market is then protected from competition to the benefit of the operators but usually to the financial detriment of the consumer public.

In the 19th century in the United States, railroad companies set their own freight rates at first. However, abusive practices soon entangled them in politics with people and business interests hurt by the

Freight Rates/Tariffs

Goods or produce that are not consumed locally may be transported for short or long distances in order to supply markets. Seeking commercial gain from the transportation of cargo or freight, whether by land or sea, has been a business activity pursued since prehistoric times on the Silk Road, the Grand Trunk Road, or any other trade route.

From ancient times, tolls were charged by governments on the goods that traveled through their

railroad freight rates. Frank Norris published *The Octopus* (1901) as a muckraking novel about the struggle between wheat growers in California and the Southern Pacific Railroad. The wheat farmers were victimized by the unwarranted rate hikes of the railroad. The railroads felt they should charge “all the traffic would bear.” This business practice was viewed as excessive by those seeking to use the railroads for shipping. In fact, it was within the limits of what customers would pay without seeking an alternative form of transportation.

Passions against railroad companies mounted soon after completion of the transcontinental railroad. As farmers grew crops, they needed the trains to ship wheat and other crops to markets but were enraged at what they believed were unscrupulous freight rates. The farmers movement between 1867 and 1896 spawned the Grange (Order of the Patrons of Husbandry), Populists, and other organizations that were successful in generating popular support for controlling the railroads, grain elevators, and other businesses that were viewed as harmful to farmers and small businesses. Legislatures and the Congress created rate-setting agencies to prevent rate gouging.

Starting in the 1870s, the railroad owners who opposed regulation sought help from federal judges and the emerging substantive due process doctrine. For the last third of the 19th century railroad cases dominated the Supreme Court’s docket. In *Munn v. Illinois* (1876) the Supreme Court allowed states to regulate grain elevator rates and intrastate freight rates. The *Munn* decision was weakened by the Supreme Court’s decision in *Wabash, St. Louis, and Pacific Railroad Company v. Illinois* (1886) in that the court restrained the power of the states to regulate interstate rates. The case stimulated the creation of the Interstate Commerce Commission (ICC).

The Interstate Commerce Act of 1887 sought to regulate the railroad industry and its business practices. The act mandated that railroad rates had to be “reasonable and just”; however, it did not empower the government to set specific rates. The act also mandated that the railroads publicize shipping rates. Differentiation between short-haul and long-haul rate fares was forbidden as a form of price discrimination against farmers and small markets. The act also created the Interstate Commerce Commission (ICC) to serve as a regulatory agency.

The ICC was a weak regulator at first because it lacked enforcement powers and because the Supreme Court interpreted its powers as limited in the light of its probusiness doctrine. During the administration of President Theodore Roosevelt changes were made. The Hepburn Act (1906) began the expansion of the ICC from railroads to all common carriers except airplanes. The ICC was also granted powers to deal with labor disputes and consolidation in the 1950s and 1960s.

In 1966 the safety functions of the ICC were transferred to the Department of Transportation. In the 1980s the deregulation movement led to the reduction of ICC supervision of rates. In 1980, passage of the Staggers Rail Act and the Motor Carriers Act further limited its powers. In 1994 the ICC was terminated and its remaining regulatory functions were transferred to the National Surface Transportation Board.

States were also active in regulating freight rates. In Texas the Railroad Commission was at first assigned the responsibility to regulate railroads, but it was later assigned responsibilities for regulating the new booming oil industry.

Other states also regulated freight rates. They called their respective regulatory agencies by different names. As the states sought to regulate the operation of transporters within their states, the variance inspired the railroads to appeal to the federal government, where a less heavy regulatory hand could be found. States could regulate in the public interest but had to do so in a manner that respected the property rights of the shippers.

Freight Terminals

Freight terminals are transportation nodes where freight or cargo is loaded or unloaded. Most freight terminals are located at ports and are intermodal, meaning that they process more than one mode of transportation—the simplest form, for instance, would be a terminal at a port where freight arrives by ship, is unloaded and warehoused, and then loaded onto trucks for delivery, or vice versa. Other modes may include aircraft and trains. Freight terminals may be ports, truck terminals located near airports, or train stations. Freight stations are train stations where freight is loaded and unloaded. They are placed both at the ends of the line and at break-of-gauge—where a railway of one gauge meets a railway of another gauge, preventing the train from continuing without converting gauges, making this a convenient point at which to move freight or passengers from one train to another, which is often faster than gauge conversion. (The major break-of-gauge still in use in the United States is in Antonito, Colorado. Most American rail systems are now standard gauge.)

Today most freight stations and many other freight terminals are transshipment terminals, meaning they handle freight that has not yet reached its destination but needs to be transferred from one vehicle to another (either from one train to another, or from a ship, plane, or truck to a train). Transshipment terminals are sometimes also called transport hubs, especially if they also handle passenger transport. When the shipment is international, transshipment usually occurs in a designated customs area, where customs checks can be performed and duties paid. For instance, cargo may arrive by freighter at a Pacific Coast port in the United States, having originated in Japan. It is inspected by the customs authority, the appropriate fees are paid, security checks are performed in order to comply with homeland security and immigration regulations,

and the freight is then transferred to other modes of freight transport, which might include freight trains, cargo planes, long-haul trucks, short-haul delivery vehicles for delivery to the local region, or other ships bound for other ports. Some transshipment ports only count ship-to-ship freight transfers as transshipment.

All ports include a seaport terminal where maritime cargo is processed. Modern cargo transport is based principally on containerization, which uses reusable containers (called intermodal containers, shipping containers, freight containers, or just “boxes” in various literature) of standardized sizes to hold freight in transit. Steel straps, wooden braces, synthetic webbing, or polyester lashes are used to keep freight in place inside a container, and air bags are inflated to occupy any empty space to prevent shifting during transport. These containers stack and lock together and, when properly packed, allow for maximum efficiency in freight movement. The containers can be transported by any mode: though they are long (typically 20, 40, 45, and 53 feet in length), their height and width are within the constraints of train and truck transport (though “high cube” containers are too tall to travel certain routes). Freight terminals where containers can be transferred from one vehicle to another are called container terminals. Most major cities and ports have a container terminal.

If the containers are not unpacked on-site or in a warehouse and are transported away from the terminal, they are loaded onto the flat bed of a truck, into a cargo aircraft, or onto a flatcar or well car of a train. Well cars are special train cars developed for container transport and can be double-stacked. Containerization is a transport solution that has solved numerous problems, simplifying the transfer of freight from one mode of transport to another by making the dimensions of freight consistent and predictable, as well as maximizing packing efficiency and accelerating the process of freight transfer on railroads at a break-of-gauge.

At any freight terminal, unloaded freight is either stored (warehoused) or cross-docked. Warehouses are an important part of ports and other freight terminals, and some are partially or fully automated, using automated conveyors, cranes, and storage and retrieval systems that respond to computer commands. Typically, goods are not stored in warehouses for long periods of time, unless they are

This seaport terminal at Port Elizabeth, New Jersey, seen here in 2010, can store thousands of standardized shipping containers at one time before they are sorted and transported to their next destinations. Containerization, an innovation that made the dimensions of freight consistent and predictable, has helped simplify the transfer of freight from one mode of transport to another.

waiting to be cleared by customs or some other regulatory body. Cross-docking has been increasingly popular, beginning in the 1930s in the trucking industry. Cross-docking is the distribution of freight from its incoming transport to outgoing transport (long-haul or otherwise) with minimal time spent in storage—often no time at all. Cross-docking facilities primarily store goods only long enough to sort them. Incoming freight may be headed to multiple destinations, and outgoing vehicles may be accepting freight from multiple origins. The storage phase of cross-docking lasts just long enough for this sorting operation to be performed, and sometimes for a vehicle to become available.

Cross-docking is key to the hub-and-spoke system, which treats a freight terminal as the hub of a metaphorical wheel, from which spokes radiate in the form of traffic from the center to destination nodes (and vice versa). Sea transport, of course, originally made this model necessary. Not every city had access to the sea and, at a minimum, freight would need to be transported from seaports (hubs)

across inland waterways (spokes), though overland routes also became common. As the railroads spread, overland transport became a more significant part of the infrastructure.

Train freight stations often include classification yards, where train cars are led down a drill track through a series of switches that divert them onto classification tracks. Classification yards sort cars according to their contents and destination. For example, trains from multiple destinations might arrive at a terminal carrying goods bound for various other destinations. Their cars are classified accordingly, such that trains can depart for their final destinations. The largest classification yards are called hump yards, with a drill track on a hill, where an engine pushes the car being classified to the top of the hill and lets it coast off the crest along its destination track. Hump yards are major operations, classifying thousands of cars a day to keep the country's rail traffic moving swiftly and smoothly.

Similarly, many cargo ships are feeder ships, transporting containers bound for various destinations

to container terminals, where they are sorted and loaded onto larger container ships bound for specific destinations. The hub-and-spoke concept at play in the function of freight terminals is familiar to most people, as it is similar to the concept used in air travel.

Freight Transport, Intermodal and Multimodal

Used since the establishment of the first trade routes between human settlements, the association of two or more modes of transport in a transport chain to convey freight is an established and regular practice. However, it was only in the second half of the 20th century that it gained wide visibility and recognition. The introduction of containers in the 1960s dramatically reduced the handling times (from weeks to days) and costs (by 5 to 10-fold) of the transshipment operations between modes of transport.

The globalization phenomenon in the 1970s demanded increasingly efficient transport chains to link the factories often located in different countries. The 1990s were characterized by a growing environmental awareness worldwide. Gradually, governments started to favor green transport solutions that could make use of sustainable modes of transport (such as, rail, sea, and fluvial transport)

over others (notably, road and air transport). Finally, the 2000s were characterized by strong economic turmoil and severe recession. In times of economic austerity, transport agents look for increased value for their money, which may be obtained by combining several modes of transport.

The rationale for the utilization of transport chains depends on the combination of several factors, including but not limited to (1) demand factors, such as, transit times, prices, or reliability levels; (2) special transport requirements for goods, such as those contingent on fragility, dangerousness, perishability, or intrinsic value; (3) the natural geographical features of the route (such as rivers, mountains, or seas) or human-made features (such as, urban regions or location of ports or airports); and (4) a legal framework that may hinder or prevent the utilization of the mode in question. As an example, Switzerland has strict legislation concerning the amount of road traffic on designated routes.

Over the years, we have witnessed a progressive specialization of each mode of transport according to its operational characteristics. Air and deep sea transport are typically used in long-distance services, often on intercontinental routes, whereas road, rail, fluvial, and coastal sea transport are used in short-to-medium-distance services, commonly on continental routes. In an intermodal transport service the actual mix of transport services depends on the abovementioned four factors, using each one at its best scale and level of operations.

The United Nation distinguishes three concepts of freight transport chains:

- *Multimodal transport*. The carriage of goods by at least two different modes of transport.
- *Intermodal transport*. The movement of goods in one and the same loading unit or road vehicle, which uses successively two or more modes of transport in an integrated and door-to-door transport chain, without handling the goods themselves when changing modes.
- *Combined transport*. An intermodal transport where the major part of the journey is by rail, inland waterways, or sea, and where any initial and/or final legs carried out by road are as short as possible.

These three concepts are in real terms only two, because combined transport is a subset of intermodal transport with a strong sustainable perspective. The key difference between intermodal and multimodal transport lies in the notion of integration. Integration refers to the existence of an active role of coordination and management of the individual transport services. This role is designated as freight forwarding.

Freight forwarding aims to exploit potential synergies and eliminate eventual frictions among transport agents. Thus, the overall performance of an intermodal transport service is higher than the sum of each individual transport service's performance. By contrast, in a multimodal transport service no integration is required, thus the overall performance is a simple summation of the performances of the individual transport services, and it is necessarily lower than that of an intermodal transport service.

The achievement of stable and efficient intermodal transport services requires an adequate integration between the individual transport services. A "transport service's profile" refers to the set of operational and technological properties of the mode of transport (such as, speed, capacity, tariffs, schedules, etc.). The relative importance of each property in the integration depends on the customer's "demand requirements" (for example, the speed property may be irrelevant in the case of nonperishable products). During transshipment operations two modes of transport interact. If their profiles are not fit (that is, the properties are not compatible, as for example, different capacities or different time schedules), losses of efficiency will occur. These losses or "types of friction" exhibit different characteristics and may occur at different moments:

- *Type 1.* Friction that provokes losses of efficiency during the production of the transport service (for example, a delay in one transport service may prevent cargo being loaded on the following one).
- *Type 2.* Friction that prevents the detection and subsequent recovery of a problem (for example, the impossibility of a fast transfer connection for delayed passengers) during the production of the transport service.
- *Type 3.* Friction that prevents the customers from being compensated for the

problems that occur during the transport service. Typically, this happens after the production of the transport service (for example, nonagreement between stakeholders on the level of customer compensation).

"Dimensions of integration" refers to the nature of the interactions that occur during the production of an intermodal or comodal transport service. Along each dimension, friction may occur and lead to losses in the efficiency of the transport service. There are five dimensions of integration:

1. Physical integration refers to the level of interoperability between modes of transport and determines the ease of transferring the goods. (For example, the transshipment of containers between deep sea ships and trains is straightforward but not feasible with aircraft, as it is necessary to manually transfer the goods.)
2. Logical integration refers to the level of interoperability between the transport agents' IT systems and determines the ease of exchanging communication. (For example, noninteroperable IT systems preclude the early detection of delays or erroneous routing of the goods.)
3. Contractual integration refers to the nature of the transport contracts that define the sharing of responsibilities among transport agents in case of delays or damage to goods. (For example, the international transport conventions define different limits of liability for each mode of transport. As a consequence, therefore, the same goods may yield different levels of compensation depending on the location of the damage.)
4. Financial integration refers to the scheme of payments agreed between the transport operators. (For example, delays of payment and fluctuation of currency may result in lower payments than initially agreed.)
5. Relational integration refers to the transport agents' willingness to participate in intermodal transport services. The optimum of an intermodal transport solution may result in a suboptimal solution for

one or more single modal transport agent, which may not be acceptable. Also, participation requires sharing sensitive information with other transport agents who are often direct competitors in the market.

Intermodal transport has received a great deal of attention in the last decades as a potential solution to curb the unsustainable growth of road transport in continental distance services. Notwithstanding, intermodal transport exhibits major difficulties in competing in the market and continues to lag behind the other transport solutions, notably road transport. European and U.S. industry data on intermodal transport reported the market share between 5 percent and 10 percent for continental-level services. These figures contrast with intercontinental services in which intermodal transport (deep sea–road, deep sea–railroad, or air–road) is the only option to convey freight to destinations that are located outside the vicinity of ports or airports.

The reasons for such chronic underperformance are well known and lie in both internal sources of friction and external barriers. The “internal sources” refer to problems arising from the combination of different modes of transport with misfit profiles. As explained above, misfit profiles generate friction along one or more dimensions of integration. The “external barriers” refer to factors of context that are not controlled by the transport agents but that influence the way they organize themselves in transport chains. Multiple barriers have been identified and still persist with more or less intensity.

Functional misalignment of the transport network happens when many existent transport infrastructures have been planned and constructed at different periods of time, with different perspectives and requirements, not always compatible (for example, the European Commission reports that a high-speed rail service through France, Belgium, Germany, and the Netherlands has to adapt to seven different signaling systems).

Fragmentation of the transport network happens frequently when planning and spatial development impose constraints on the construction of transport terminals or infrastructures, resulting in suboptimal transportation systems, which are often not connected. Another problem occurs

when legal frameworks are modal specific and do not foresee multimodal arrangements, which leads to difficulties in case of conflict. Institutional separation by mode of transport occurs when public concessions for operating transport networks are modal based, which creates barriers to the construction and operation of multimodal transport networks. The actual mix of internal sources and external barriers will influence the risk of failure and the level of instability of the intermodal transport service.

Freight Transport, Security Issues

Transport planners and managers have wrestled with transport safety and security issues for years, but the terrorist attacks on the United States on September 11, 2001, catapulted the issue of physical security of goods to the forefront and elicited a response that has transformed the way goods are moved across America and the rest of the world in unprecedented ways.

Besides circumventing terrorist attacks, transported goods also need to be secured against threats to health, for example, accidents involving hazardous materials that disperse them over densely populated areas. Security concerns not only affect transporting goods by air, land, and sea but also the terminals where they are stored.

Terminals as Targets

Since railway stations and airports are some of the most densely populated transportation centers, managers have long been concerned about the safety of goods stored in their terminals. Traditionally, freight industry concerns have centered on worker safety and theft, because freight terminals are dangerous places to work. Every day in freight yards across the country, large machines and sweating workers load heavy goods onto vehicles, running the risk of numerous accidents. Worker education and improved methods of operation have made conditions safer over the years, but freight terminals are still dangerous places to work.

Thefts have been a constant and severe problem confronting freight terminals and, over time, companies have restricted access to them and used security staff (or contractors) to help control thefts. As globalization produced global supply chains, freight transport security emphasis is transforming into a more comprehensive and multilayered approach, with a particular focus on cargo integrity and the use of computer information systems to manage the supply chain. Establishing procedures to preserve the cargo, such as inspections, and to secure facilities, personnel, and data are also important measures.

Air Freight Security

Statistics from the Transportation Security Administration (TSA), an agency of the Department of Homeland Security established in 2001 to safeguard U.S. transportation systems and ensure safe air travel, illustrate part of the magnitude of monitoring air freight security. There are 19,576 general aviation airports, heliports, and landing strips across the United States and 459 commercial airports. The aftermath of September 11, 2001, created a new set of security issues and amplified the scale and scope of regulations and monitoring of cargo companies.

In 2010, the TSA introduced new regulations that mandate the screening of all domestic and

international air cargo in the United States before it is loaded. The Certified Cargo Screening Program requires airlines, freight forwarders, and shippers to pay for security measures as part of its program of establishing a secure air freight transport chain. This additional security mandate adds another problem to the air cargo industry, which is already coping with higher energy costs and weak demand. Several freight forwarders use maritime shipping facilities instead of air cargo for long-distance shipping, an unusual combination of shipping by both air and sea.

Maritime Transportation

There are 25,000 miles of commercial waterways in the United States, 361 ports, and 9 million containers passing through 51,000 ports of call. Maritime transport accounts for at least 80 percent of global trade and includes significant amounts of dangerous commodities—weapons, narcotics, ammunition, and other hazardous materials. The monitoring and security of maritime containers is complicated by the difficulty of detecting problematic containers, the global nature of the shipping industry, and the presence of terrorists and pirates.

The shipping container, the facilitator of globalization, makes it difficult to identify illicit or dangerous cargoes. Without scanners that can inspect the entire contents, each container must be checked manually, which is time consuming and an enormous task because of the large volumes of shipping. The growing international practice of hubbing—accumulating export and import cargoes at selected hubs from which to forward to their destinations—exacerbates the problem because hubbing requires multiple containers to be handled with minimum delays and inconvenience. Hubbing also increases the opportunity for sabotage.

In 2002, with the backing of the Department of Homeland Security, the United States enacted the Maritime Transportation and Security Act, and the International Maritime Organization adopted the basic elements of this legislation. The important provisions of this act include the requirement of installing an automated identity system for all vessels between 300 and 50,000 dead weight tonnage, ordering vessels to display a permanently marked and visible identity number, and requiring ships to have current records of flag, port of registry, and addresses of the registered owners.

A U.S. Customs and Border Protection officer, situated on top of a shipping container on board a vessel, opens a container panel for search and inspection at the Port of New York and New Jersey in Newark, New Jersey, November 6, 2012.

Another stipulation of the Maritime Transportation and Security Act states that each port must conduct a security assessment of its assets and facilities and estimate the effects of damages from a possible terrorist attack. The port must identify and evaluate the risks to and weaknesses in its physical security, communications system, utilities, and other resources. Another stipulation of the Maritime Transportation and Security Act is that all cargo destined for the United States must clear customs before the ship leaves port. There is also a move to establish biometric identification and an international database of sailors. The act is being implemented in ports around the world, and an uncertified port will find it difficult to trade with the United States, making security an important part of a port's competitiveness.

In 2008, Department of Homeland Security legislation required all containers shipped to the United States from foreign ports to be screened. Foreign ports must use gamma and X-ray scanners to examine all U.S.-bound containers, no matter what the security threat, causing more financial and operational obstacles for foreign countries wanting to trade with the United States.

The Department of Homeland Security's Container Security Initiative (CSI) allows U.S. Customs

and Border Protection (CBP), working with participating governments' customs services, to examine high-risk maritime containerized cargo at foreign seaports before it is loaded onto vessels that are bound for the United States. In 2012, more than 58 foreign ports participated in the Container Security Initiative, accounting for 85 percent of container traffic bound for the United States.

Freight Rail Security

The Federal Railroad Safety Act of 1970 defined railroad safety in the decades before 9/11. By the 1980s, the rail freight industry had been largely deregulated, and it prospered without too many safety issues. After 9/11, the TSA took over railroad security, affecting the ability of the railroads to control their own operations while ensuring security against terrorist attacks.

In a 2009 study titled "The Highlights of Freight Rail Security Actions in the United States Since the September 11, 2001, Terrorist Attack," which it conducted for the TSA, the U.S. Government Accountability Office (GAO) explored the probable effects of a terrorist attack on the U.S. freight rail system, which operates over 120,000 miles of major railroads. The U.S. rail system is an attractive terrorist target because it is publicly accessible, features long stretches of open and unattended track, and an attack could produce a catastrophic loss of life because the railroads cross densely populated urban areas. According to the Department of Transportation (DOT), freight rail is the major carrier of highly hazardous materials in the United States, typically hauling from 1.7 to 1.8 million carloads of hazardous materials a year.

The study examined the security status of the freight rail system, the actions that the railroads had taken to secure the system since 2001, and TSA's efforts to monitor and assess the effectiveness of any security precautions. The GAO recommended that the TSA focus on other areas of concern besides railroads transporting hazardous materials, including risks to critical infrastructure and cybersecurity. Pointing out that the freight rail industry has taken action to secure shipments and key infrastructure, the study recommended that the TSA create a mechanism to track security improvements on the railroads and assess their effectiveness. The TSA will strive to develop baseline security standards for all rail systems, assess operator security

status versus existing standards, develop a plan to close gaps in security standards, and enhance existing security standards.

Truck Security

Before 9/11, security concerns in the trucking industry tended to focus on variations of crime, cargo theft, and trucking or driver safety. With a few exceptions, like the Oklahoma City bombing on April 19, 1995, trucks have not been a typical target or weapon for terrorism. After the world-changing September 11, 2001, terrorist attacks, law enforcement personnel, national security analysts, and the U.S. Department of Homeland Security acknowledged that the trucking industry does indeed offer some important attractions to terrorism. These attractions include access, sizable volume, relatively cheap and viable energy, a vast operational environment, indispensability, and commonality.

More than 80 percent of U.S. communities depend solely on trucks for the products and goods they receive, including food, books, clothing, electronics, automobiles, and medical supplies. These trucks travel 3.9 million miles of public roads, and keeping trucks and their cargo safe is one of the TSA's security responsibilities, although the individual states and their authorities play an essential role in ensuring general security as one of their basic operating responsibilities.

In 2009, the American Trucking Association (ATA) published the *ATA Certified Cargo Security Professional Resource Guidebook*, a 186-page manual that helps readers evaluate and manage risk and trucking security from pickup to delivery. Developed by the ATA's Security Council, the book provides a security blueprint for facilities, personnel, information, and computer security. It covers federal security regulations for hazardous materials transportation, cross-border security, and intermodal security.

The International Road Transport Union focuses entirely on security measures against terrorism. In its *Transport Security Guidelines*, the group states that the goodwill and active participation of local and state authorities are essential to the success of any security program. Keeping trucks and hauling vehicles safe is a balancing act. If security procedures are too stringent, the business of transporting goods could be stalled, drastically disrupting the U.S. economy and giving terrorists a victory, while lax security measures will give them an opportunity

for an attack. Transportation companies must balance a sensible and sensitive middle line and never forget that zero risk does not exist and total security can never be guaranteed.

Freight Transport Models

Globalization, economic development, and new information technologies have been spurring consumption and trade among nations. Available forecasts predict significant growth in freight demand

in many regions worldwide in the coming decades. Such growth is likely to generate significant impact on the current transportation systems (in terms of congestion and accidents) and the environment (in terms of increase of emissions of greenhouse gases and depletion of natural resources). There is therefore the need to increase the efficiency and promote the sustainability of freight transport systems and to mitigate the conflicts with other users (including private cars, bikers, and even pedestrians).

The identification of adequate solutions often requires field experimentation of new concepts and multiple alternatives. However, field experimentations in transportation require a significant amount of resources (human, equipment, capital, etc.) without any real assurance of return, besides inevitably introducing disturbance or disruption into the transport systems. It is at this moment that models can be quite useful. Models are cost-efficient alternatives to field tests and provide fully controllable environments for testing alternative hypotheses and scenarios.

A model is a simplified representation of a real-world situation (although it can also be used to study imaginary conditions). It contains the minimum amount of detail (in terms of variables, features, or detail) to adequately permit the study of the problem. The simplification is required for reducing the complexity of the real world to manageable levels for an efficient development of the model. However, simplification also denotes that particular aspects of the real world are not considered in the analyses. Therefore, the outcomes of a model are by definition inaccurate or, in other words, have a degree of uncertainty, which tends to increase with the level of simplification. Even so, models have proven very useful to forecast demand for transport services and to estimate the impact of changes in the transportation system.

Passenger transport models are more established and developed than freight transport models. Understandably, the primary political and societal interest was on improving the transport of people, which eventually drove academic endeavor. Indeed, the initial freight transport models were inspired by the passenger models. Yet people and freight exhibit significantly different transport patterns and behaviors, and before long, the need for tailor-made models was recognized.

Freight transport models have been applied to a wide variety of geographical areas, ranging from the city district level up to the continental level. The size of the geographical area is relevant in the modeling process because it influences the zoning. Zoning is the process of dividing the geographical area of study into a set of smaller regions—zones. The modeling parameters are considered homogenous within each zone. They are normally equal to the average value of some of the individual elements of each zone. Zoning thus reduces the inherent complexity of the real world to a manageable level. As it introduces errors in the analysis, the number and shape of the zones should be carefully considered.

The European Union–cofunded research project SPOTLIGHTS-TN identified a total of 65 freight transport models and 29 joint passenger and freight transport models in a universe of 222 transport models. Compared with the passenger side, freight transport modeling lags behind considerably. Even so, substantial progress has been achieved and there is now a rich assortment of models. Typically, classification is done according to their primary purpose, as discussed below.

Models for Production/Attraction of Freight

The purpose of these models is to estimate the amount of freight produced and consumed in every zone. Several models have been developed. Trend and time series models use historical data to build correlation function and to extrapolate future values. Multiple methods have been proposed to build the correlation functions. As an example, the growth factor method uses a multiplier to convert past data into future values. Multipliers can be obtained through interviews with experts, economic correlations, or even past trends. Other more complex approaches include, for example, autoregressive correlations.

A similar method—zonal trip rate models—relies on collected data of traffic volumes leaving or entering the zones. The detail of the data is case-specific but may include, besides volumes and quantities, trips per mode of transport, the nature of the goods, or the origin and destination of locations.

Economic models rely on regional economic activity to estimate the production and consumption of goods in each zone. These models are, in many developed regions, developed by the national statistics offices.

The ASTRA—assessment of transport strategies—model uses a system dynamics approach to link the growth of gross domestic product (GDP) at the national level to the freight transport demand at the regional level.

Models for Distribution

The purpose of these models is to determine the flow of goods between each pair of zones. The results are normally presented in a table format (see Table 1), designated as an origin–destination matrix (OD matrix). Each cell contains the estimated freight conveyed from the origin zone to the destination zone.

Gravity models are the most commonly used methods to determine the flows. These methods are inspired by the well-known gravitational law that states that the attraction between any two bodies is the function of the production of their masses divided by the square of the distance between them. Gravity models state that the flow X_{ij} is the function of the product between the production at the origin O_i and the attraction of destination D_j divided by the impedance to moving the freight between O_i and D_j . Production and attraction are normally measured using the above models for production and attraction of freight. Impedance is normally measured by a transport cost function. Transport cost functions may cover a wide range of resistance to transport, specifically, distance, tolls, taxes, transshipment operations, etc. These methods have limited data requirements and allow the assessment of transport policies through the transport cost functions. Conversely, the scope for including explanatory

variables is rather limited and the number of calibration parameters is limited. The Dutch TEM-II model uses a gravity model.

Economic models are another method to determine the distribution of the flows. These methods, described in the previous section, use the economic data to determine the supply and demand of freight of each zone (output of the models for production and attraction of freight) and respective distribution between zones. These methods have the advantage of being linked to regional economy and land development. They can provide information on the transport and land use interactions and, in specific circumstances, be used to assess policy effects. However, they require a substantial amount of data with a level of detail that is often difficult to obtain. Furthermore, these methods utilize tons while many available statistics report the freight in value. In such cases, a transformation of value into tons is required. Examples include the Strategic Transport Research for European Member States (STREAMS) project and the Scenarios for European Transport Models (SCENES) project.

Models for Modal Split

The purpose of these models is to allocate freight flows (between each pair of zones) to the available transport services. The transport services can be either single modal (for example, road, train, or sea) or intermodal (for example, road and train, or road and sea). It is important to note that the available transport services depend on the available transport infrastructure and transport operators and, thus, they may change between pairs of zones. A wide set of models are possible. Economic models are normally grounded in the theory of the firm. They build the transport agent cost function, in which the available transport services are considered as one of the inputs. Demand functions, based on the costs function, can then be derived. Tae Oum presents a freight transport model using this approach.

Disaggregated modal split models represent the shipping firm's decision-making process. They are grounded in the assumption that shipping firms are rational and will opt for the transport solutions that maximize their benefits or utility. Utility functions are then built for typologies of firms, normally using the multinomial logit or the nested logit methods. These methods require a substantial amount of data, which may not be

Table 1 Origin–destination matrix

		Destination Zones			
		D_1	D_2	...	D_n
Origin Zone	O_1	X_{11}	X_{12}	...	X_{1n}
	O_2	X_{21}	X_{22}	...	X_{2n}
	...	...	...	...	...
	O_m	X_{m1}	X_{m2}	...	X_{mn}

Source: Vasco Reis

readily available. Typical sources include surveys of companies and transport companies, and available statistics on freight flows. Gerard de Jong and colleagues present a freight transport model using this approach.

Aggregated modal split models estimate the average market share of the transport services. These models, rather than modeling the decision making of individual firms, rely on available statistics (modal share for a number of zones) to infer the utility functions, normally in the form of the binomial or multinomial logit models, of each transport service. The validity interval of the utilities functions is therefore limited to source zone flows. These models have limited data requirements. However, since they work with average values, they provide little information on the causality effects underlying the results. Gust Blauwens and Eddy Van de Voorde present a freight transport model using this approach.

Models for Trip Assignment

The purpose of these models is to allocate vehicle trips to the transport services. This requires a diversified amount of information, including vehicle capacity, schedules, or occupancy levels. In the case of road transport, it also involves assigning trips to paths and links—routes. Since freight vehicles share the infrastructure network with passenger vehicles, often both assignments are simultaneous—traffic assignment. These models assume that the agents behave rationally and choose the paths with lower costs. As such, the equilibrium of a network is obtained when no vehicle can change a route without increasing its costs. Limited capacity of the road network and therefore congestion problems can be considered with the introduction of penalties (such as an increase in transit time or an increase in fuel consumption).

An important aspect is related to driver access to information about the network congestion levels (present and future). Some models consider that drivers have full access to information, while other models consider that drivers only have partial access. In the latter case, drivers can make decisions based on outdated information and may end up choosing links that are congested. These situations lead to suboptimal situations being closer to reality, in which drivers have no knowledge of the network and respective traffic conditions. The STAN

and NODUS are two well-known models for trip assignment.

Other Models

Many models embrace several or all of these functions. The four-step model, for example, is arguably the best known modeling concept for both passenger and freight transport models. The modeling concept was initially developed for passenger transport but was soon adapted for freight transport. The name results from the model being structured in four sequential steps, which correspond to the above-mentioned models, that is, production and attraction, distribution, modal split, and assignment. The popularity of this concept is due to the simple and easy-to-understand organization.

Other models embracing several functions are the national freight transport models. These models are commissioned by the national governments to support transport-oriented policy development. These include the Dutch Strategic Model for Integrated Logistic Evaluation model (SMILE), the Swedish SAMGODS model, or the Norwegian Network model for freight transport within Norway and between Norway and other countries (NEMO). The European Commission financed the development of the European Transport Network model Tools for Transport Forecasting and Scenario Testing (TRANS-TOOLS).

Full-Feedback Modeling

Transportation planning and the need for travel demand models has been recognized by urban planners and researchers for over a century. Transportation modeling has been used for infrastructure planning and policy analysis for decades. The planning process requires estimates of current use of a surface transportation system, including highway, transit, nonmotorized, and freight modes. Travel forecasting models are used to study proposed investments in the transportation system and determine which of these investments will best serve the public's needs for future travel and economic development. The models are also used to determine air quality impacts of proposed transportation projects, to evaluate the impacts of alternative land use, and to forecast energy consumption.

With passage of the 1990 federal Clean Air Act Amendments (CAAA), the 1991 federal Intermodal Surface Transportation Efficiency Act (ISTEA), and the National Environmental Policy Act (NEPA), a resurgence of interest in improving travel demand model behaviors and forecasting techniques has been evidenced throughout the country. The federal government, state transportation agencies (STAs), and metropolitan planning organizations (MPOs) have historically shared responsibilities for developing transportation models and making urban travel forecasts.

Initially, federal agencies took the lead in developing travel forecasting methods; over time, these responsibilities have shifted to the states, MPOs, and the private sector. The federal government has not become invisible with respect to metropolitan travel forecasting, however. A travel forecasting process with which to estimate travel impacts and facility needs is necessary to meet the requirements of federal laws, such as those mentioned above. In fact, every urban area in the United States with a population of 50,000 or more must undergo a metropolitan transportation planning process as a precondition for federal funding of transportation projects.

Travel Demand Models

A transportation model, also known as a travel demand forecasting model, is a computer-based mathematical model that simulates supply and demand for travel in a given (usually urban) area. Models are used in a sequence of steps to answer a

series of questions about future travel patterns. The basic questions asked in each transportation modeling step are as follows:

1. What will our community look like in the future?
 - a. How many people will there be?
(population forecasts)
 - b. What will they be doing?
(economic forecasts)
 - c. Where will activities take place?
(land use)
2. What will be the travel patterns in the future?
 - a. How many trips will be made?
(trip generation)
 - b. Where will the trips be?
(trip distribution)
 - c. What modes will be used?
(mode split)
 - d. What routes will be used?
(traffic assignment)
 - e. What will be the effects of this travel?
(impact analysis)

These models are highly complex and require (as inputs) extensive current information on roadway and transit system characteristics and operations, as well as current and forecast demographic information. Creating and operating the models requires a high degree of technical training and expertise. Once a model is developed that replicates existing travel conditions, future conditions and alternatives can be evaluated in terms of their impact on the transportation system.

The most common paradigm for travel demand models in the United States is known as the "four-step model" (FSM) due to its four main steps: trip generation, trip distribution, mode choice, and trip assignment. This model is known as a trip-based model (TBM). The travel supply is generally represented by a highway network and a transit network. The highway network represents all major roads in the region and the transit network represents all public transportation service in the region, such as bus, rail, and commuter rail.

The demand for travel is developed using a series of mathematical models. The first three steps of a trip-based FSM travel model are used to estimate

the demand for travel. In the fourth step, trip assignment, the travel demand is equilibrated with the travel supply, as trips are loaded onto one or more transportation networks. The geographic unit of analysis in a four-step model is the transportation analysis zone (TAZ). Usually an urban area is divided into hundreds or thousands of transportation analysis zones.

In the past decade, planners and policy makers have begun asking more complex questions, such as: How might rising fuel prices affect the choice of locations for living, working, shopping, and leisure activities, or travel behavior? What impact do road use charges have on vehicle types, occupancy, peak-hour travel, or level of congestion? What are the impacts of alternative development scenarios, such as smart growth strategies, on traffic volumes? How do rising freight volumes impact traffic flows at different time-of-day periods? These and other questions asked by policy makers are difficult to answer with traditional modeling approaches. New methods of transportation modeling have been developed and are now increasing in use.

An alternate approach to the trip-based model is the activity-based model (ABM). Although academics and researchers have been studying ABMs for years, it is only recently that some urban planners have begun to develop or adopt activity-based models. Whereas trip-based models use the trip as the basic unit of analysis, ABMs assume that travel is a derived, or produced, demand (from the need to participate in various activities throughout the day) and use a combination of trips and tours (collections of linked trips beginning at home) as the unit of analysis. Tour-based models overcome much of the knowledge loss associated with trip-based models because these trips in the model “have some knowledge” of their context. Both TBMs and ABMs have been successfully used over the years to address policy and investment options at urban and statewide levels.

More Recent Models

Other models that have been used more recently are land use models, freight and commercial movement models, and statewide models. Land use models are used because they test land use policies and they can be integrated with travel models to simulate the interaction between them. New transportation infrastructure affects land use patterns;

the transportation/land use feedback cycle explains how transportation influences land use and how, in turn, land use creates transportation demand. Integrating a transportation model with a land use model implements the entire feedback cycle, which helps account for induced travel demand.

Commercial movement models have been implemented to account for their growing share of traffic congestion. Freight and commercial vehicles react quite differently to many transportation policies and network conditions. These trips may be more sensitive to changes in travel time, requiring models that more appropriately account for these differences. Statewide models have been implemented to analyze policies at the regional level. For example, development of a new roadway may assist in local traffic patterns but cause travel difficulties on longer routes. Regional models take into account the scope of a larger picture beyond the often artificial boundaries of a city.

The traditional four-step, trip and activity-based model provides a mechanism to determine equilibrium flows. First, in trip generation, measures of trip frequency are developed, providing the propensity to travel. Trips are represented by beginning and end points, or productions and attractions, which are estimated separately. Next, in trip distribution, trip productions are distributed to match the trip attraction distribution and to reflect any underlying travel impedance (such as time or cost), yielding trip tables of person-trip demands. Next, in mode choice, trip tables are essentially factored to reflect relative proportions of trips by alternative modes. Finally, in route choice, modal trip tables are assigned to mode-specific networks.

Time of day is typically introduced after trip distribution or mode choice where the production-attraction tables are factored to reflect observed distributions of trips in defined periods (such as the A.M. or P.M. peaks). Total demand, as specified through generation, distribution, mode choice, and time-of-day models, is fixed, with only the route decision to be determined. Most applications of the FSM feedback equilibrate link travel times to the mode choice or trip distribution models for a second pass through the last three steps. Integrated land use and transportation models are absent in most U.S. applications, and although they have gained some popularity, most metropolitan planning organizations still use the four-step model.

The FSM falls short, as the demands on forecasting models have grown significantly in recent years. Existing models are inadequate to address many new policies, such as estimating motor vehicle emissions and evaluating alternative land use policies. The four-step model is inherently weak in that it does not address individual travel behaviors. It cannot be expected to represent the conditions of an individual traveler choosing how, when, and where to travel. As a consequence, time chosen for travel, travel behavior, time-specific traffic volumes and speeds, freight and commercial vehicle movements, and nonmotorized travel cannot be accounted for accurately.

Improvements to the FSM have been made in recent years. In some cases models can be modified to accommodate additional factors or procedures, while in other cases major modifications are needed or new software is required. The following are some potential modifications of models that may help improve their usefulness: better data, that is, recent data that represent all components of the population to use to calibrate the models and to provide for checks of their accuracy; improved representation of bicycle and pedestrian travel; better vehicle occupancy models; better time-of-day procedures; more trip purpose data (market segments); better representation of access; incorporation of costs into trip distribution; add land use feedback; add inter-section delays.

Funicular Railways

Funicular railways combine the elevator operating principles of a cable pulling a car upward with the railroad technology of a car on a track with a haulage cable controlling its movements. For centuries, countries all over the world have used funicular elevators and railroads on inclines to transport people and goods up steep hillsides and in modern times to carry skiers up and down mountains. Although funicular railways still operate worldwide and new ones are still being built, the technology dates back to the 16th century. Modern funicular builders use technologically advanced materials, built on the foundation of the historic funicular concept. Funicular railways operating in the 21st century were created and are operated in as many different ways as the sizes and shapes of the passengers that ride them.

Innovative Funicular Railways

The city of Dana Point, California, operates the Strands Beach Funicular, which since 2009 has carried people between the beach and the top of the hill overlooking it. Closely resembling an inclined elevator, the Strands Beach Funicular is powered by an electric motor on the car itself and it runs on a

cog rail system. The car can carry up to eight passengers and it provides easier access to the beach for the public and disabled people. The Strands Beach Funicular travels about 2 to 3 miles per hour.

A funicular called the Normal Railroad, or Western Trolley, operated on the campus of Western Michigan University in Kalamazoo, Michigan, from 1908 until 1949. In the early 1900s, the main campus of Western Michigan University, then called the Western State Normal School, stood on Prospect Hill—now known as East Campus. Students and teachers had to climb up 150 steps to reach the building in both good and bad weather, so the school administration built a funicular railway along the northeast corner of the hill with two tracks, each with a car hauled by a cable. At its peak the railroad carried 2,280 passengers a day, but eventually rising maintenance costs combined with the popularity of the automobile destroyed the funicular and it closed in 1949.

In 2002, at Western Michigan University, four senior engineering majors decided to build an operational replica of one of the trolleys, a difficult task because a bench that a faculty member had saved was the only artifact left from the original funicular. Although sketches and photographs had survived, there were no blueprints of the original funicular. Overcoming all obstacles, the engineering students unveiled the replica trolley on April 8, 2003, and it occupies a prominent place on Western Michigan University's main campus. Western Michigan students, alumni, and local residents ride the funicular and testify to its authentic restoration.

The Fenelon Place Elevator began in the imagination of banker J. K. Graves, who lived on top of the Mississippi River bluffs in Dubuque, Iowa, and worked at the bottom. Every day he spent hours driving his horse and buggy back and forth to work. As a traveler Graves had seen incline railways in Europe, and he believed that a funicular railroad would ride the Dubuque bluffs well. He petitioned the City of Dubuque for the right to build a railroad and the city granted him the franchise on June 5, 1882. He hired local engineer John Bell to design and build a one-car cable patterned after the cable cars in the Alps.

The original Fenelon Place cable took its first trip on July 25, 1882, and after that Graves had his gardener send him down in the car in the morning, bring him up at noon, down after dinner and his

nap, and up again at the end of the workday. Before long, his neighbors joined him and grew to depend on the Fenelon Place Cable to commute to work, shopping, and church.

Eventually Graves gave the franchise for the track right-of-way to 10 of his neighbors who banded together and formed the Fenelon Place Elevator Company. The members of the Fenelon Place Elevator Company traveled to the 1893 World's Columbian Exposition in Chicago, Illinois, to look for material for their funicular, and they brought back a streetcar motor to run the elevator, the turnstile, and steel cable for the cars. They also installed three rails with a fourth bypass in the middle to allow for the operation of two counterbalanced cars.

In 1897, C. B. Trewin built a house next door to the elevator, and by 1912 he had become the sole stockholder of the Fenelon Place Elevator Company because the original 10 stockholders had died or moved away. His family has owned and operated the elevator since then. In 1977, the cable cars were completely rebuilt and, after 84 years, the owners replaced the original gear drive with a modern gearbox with a DC motor. The elevator anchors a shopping district called Cable Car Square.

Angels Flight, Los Angeles

Angels Flight, a funicular railway located in the Bunker Hill district of downtown Los Angeles, California, has two funicular cars: Sinai and Olivet. The funicular operated on two different sites with the same cars and station elements. The original Angels Flight operated from 1901 until 1969, when its site was cleared for redevelopment.

Colonel J. W. Eddy and other backers operating as the Los Angeles Incline Railway, financed Angels Flight, which became the railway's official name in 1912 when the Funding Company of California purchased the railway. The original Angels Flight had two cars connected to the same cable, and although it didn't have track brakes, it did have a separate safety cable in case the main cable broke. It operated safely for 68 years.

The first Angels Flight closed in 1969, after Los Angeles city planners decided that the Bunker Hill area needed complete redevelopment to replace the older, shabbier buildings with a modern mixed-use district of commercial buildings and modern apartment and condominium complexes. The Los Angeles Incline Railway put the components of Angels

Flight in storage until the railway could be restored and reopened.

The second Angels Flight opened a block south of the original site in 1996, with its tracks connecting Hill Street and California Plaza linking the city's Historic Core and Broadway Commercial District with the Bunker Hill California Plaza urban park on the hilltop and the Museum of Contemporary Art. On October 13, 2000, Angels Flight was added to the National Register of Historic Places, but then, on February 1, 2001, disaster struck. Angels Flight car Sinai reversed direction while approaching the upper station and accelerated downhill and struck car Olivet near the lower terminal, killing one person and injuring seven others.

The National Transportation Safety Board (NTSB) investigated and found that improper design and construction of the Angels Flight funicular drive and failure of regulatory agencies to enforce funicular safety standards had caused the accident. After repairs and repeated testing of its new drive and safety systems, the NTSB and the California Public Utilities Commission approved the safety certificate for the railroad to reopen on March 15, 2010. Just over a year later on June 10, 2011, the California Public Utilities Commission ordered Angels Flight to immediately cease operations because the steel wheels on the two cars were dangerously worn. Inspectors discovered that the 15-year-old wheels needed replacing, and Angels Flight reopened on July 5, 2011, after workers installed eight new custom-made steel wheels on the two cars.

Pittsburgh and Johnstown

The funiculars in Pittsburgh were built with public money for public use and operated by the local transit authority. Pittsburgh enjoyed an industrial boom in the 1860s and a demand for labor attracted German immigrants who needed housing. Since factories sprawled over the flat lands near the Monongahela River, people built houses on the steep hillsides above the river where no good roads or public transportation existed. The German immigrants remembered their *seilbahns*, or cable cars, at home and they suggested constructing inclines to carry people up and down Mount Washington and other hills.

Built in 1870, the Monongahela Incline is the oldest continuously operating funicular in the United

A view of the Duquesne Incline funicular showing the cables running between the rails on Mount Washington in Pittsburgh, Pennsylvania, in 2007. The 1877 Duquesne Incline nearly closed for good in 1962 but was saved by a community-based effort.

States and, along with the Duquesne Incline, survives from the original 17 funiculars built in Pittsburgh. The Port Authority of Allegheny County operates the Monongahela Incline, and transfers from the light rail and buses can be used on the funicular. Its lower terminal is located across the street from the Station Square shopping complex.

Opened in 1877, the Duquesne Incline scales Mt. Washington and is located near Pittsburgh's South Side neighborhood. In 1962, the Duquesne Incline closed, supposedly for good, because it had few patrons, needed major repairs, and its private owners were not interested in continuing it. Duquesne Heights residents conducted a fundraiser to save their funicular, formed a nonprofit organization to preserve it, and it reopened on July 1, 1963. It is one of Pittsburgh's most popular tourist attractions and local residents use it to commute to school and work.

Advertised as the world's steepest vehicular inclined plane, the Johnstown Inclined Plane carries automobiles and passengers between the city of Johnstown and the borough of Westmont on Yoder Hill. After the catastrophic flood of 1889, citizens of Johnstown searched for an escape route from future

floods and convenient transportation from Johnstown to the new communities above the valley. After its opening in 1891, the Cambria Iron Company and its successor, the Bethlehem Steel Company, operated the Johnstown Inclined Plane until 1935, when they sold it to the borough of Westmont. It underwent major renovations in 1962 and from 1983 to 1984, and in 1994 it was designated a Historic Mechanical Engineering Landmark. In 2011, the Johnstown Inclined Plane had a ridership of 81,236 passengers.

Future Planning

Traditional funiculars were enclosed vehicles running up and down a mountain, but funiculars in Cincinnati were different. They were just gated platforms fairly level to the horizon, with entrances and exits aligned with the existing street grid instead of the sidewalk. This pared-down design allowed horse-and-wagon teams to board the funicular from the street below, travel up the mountain, and enter the street above with little effort. As technology progressed, streetcars, trolleys, and buses did the same thing.

Cincinnati's funiculars and their design concept vanished with the dominance of rail transit systems, buses, and private automobiles, all of which could almost effortlessly scale mountains. Rail systems, including light rail, streetcars, and subways,

are technologically limited by how steeply they can climb, which restricts their operation to mostly flat locations, but when they are partnered with a Cincinnati-styled funicular, they can exponentially expand their range of operations. Municipalities considering installing light rail transit systems might well study Cincinnati-style funiculars.

Gasoline, Reformulated

Gasoline is currently the fuel that powers most vehicles traveling on streets and roads. Gasoline generates energy by changing a hydrocarbon (which is comprised solely of hydrogen and carbon) to water and carbon dioxide (CO_2). Because gasoline is a fossil fuel derivative, combustion leads to the emission of noxious pollutants into the ambient atmosphere. As the number of cars on the road (and vehicle miles driven) increases, the resulting pollution worsens. This is especially problematic in places with high vehicle density. To mitigate this problem, some cities or regions have been requiring the use of reformulated gasoline. Reformulated gasoline is designed to burn cleaner, reducing the amount of potentially dangerous emissions and smog-forming chemicals to the air.

Characteristics

Gasoline is a volatile substance. Volatility, the propensity of a chemical substance to evaporate under normal thermal and pressure conditions, is a function of vapor pressure. One typical way of evaluating how volatile a fuel can be is by its Reid vapor pressure (RVP), which describes the rapidity with which fuels evaporate. Larger (smaller) values indicate greater (lesser) volatility. Measured in pounds per square inch (psi), there is no single satisfactory value of RVP for gasoline, as a suitable value

depends on temperature (and by extension, season of the year). For example, a reduced volatility may be desirable under hot conditions, as it decreases the potential for vapor lock to occur. On the other hand, increased volatility under cold conditions makes it easier to start an automobile. In the United States, RVP standards must be met during summer by conventional gasoline.

Although gasoline is derived from crude oil, it contains numerous additives. These include such substances as toluene (to boost octane) and benzene (as an antiknock agent). Both gasoline's fundamental constituents, as well as the extra additives, contribute to the soup of unwanted chemicals emitted into the surrounding air.

Reformulated gasoline is gasoline that has been modified to lessen the toxic emissions released to the surrounding atmosphere. These discharges include nonmethane hydrocarbons (NMHCs), carbon monoxide (CO), and nitrogen oxides. The latter are nitrogen monoxide, also known as nitric oxide (NO) and nitrogen dioxide (NO_2); collectively, they are commonly referred to as NO_x . Carbon monoxide is one of the most noxious by-products of fossil fuel combustion, and the dangers of breathing concentrated amounts of this gas in enclosed areas are commonly known. Nitrogen oxides result from nitrogen and oxygen reactions occurring during the combustion of fossil fuels such as gasoline.

A cleaner burning fuel also needs to be usable by standard automobile engines. Reformulated gasoline is safe enough to use without affecting engine performance. Many major automobile manufacturers, including General Motors, Ford, Mitsubishi, and Nissan, support and endorse the use of the oxygenated fuels (fuels that have oxygen added to burn cleaner), noting the environmental benefits. Other manufacturers, while not issuing outright endorsements, note that oxygenated fuels may be used, though typically stating a disclaimer that ethanol (the oxygenating compound in some fuels) content be no more than 10 percent by volume. Additionally, there is no danger of engine or fuel system damage if users of reformulated gasoline switch to conventional gasoline in locations where the altered fuel is unavailable; the converse is true as well.

Policies to Reduce Risk From Emissions

Recognizing both environmental problems and air pollution risks to human health, the United States created the Clean Air Act in 1970 (it was signed into law by then president Richard M. Nixon). In 1990, the U.S. Environmental Protection Agency (EPA) amended the Clean Air Act to address the issue of low-level tropospheric pollution by strengthening existing provisions as well as instituting new concepts and directives. These were designed with the aim of reducing air pollution, especially that which related to traffic and the use of motor vehicles. One such new provision required the use of reformulated gasoline in nine regions that were particularly hard hit by smog and air pollution. Regions that were out of compliance with the ozone level set by the National Ambient Air Quality Standards (NAAQS) were obligated to sell reformulated gasoline by January 1, 1995, based on the initial phase of the Clean Air Act's amendments. The nine metropolitan regions deemed by the EPA to mandate the sale of reformulated gasoline in Phase 1 were identified based on levels of ozone. Those regions were Baltimore (Maryland), Chicago (Illinois), Hartford (Connecticut), Houston (Texas), Los Angeles (California), Milwaukee (Wisconsin), New York City, Philadelphia (Pennsylvania), and San Diego (California). Reformulated gasoline was also required for use in several (smaller) U.S. states—Connecticut, Delaware, Massachusetts, New Jersey, and Rhode Island—as well as the District of Columbia. This

program, however, was not limited to the mandatory regions. Additional metropolitan areas could join the program voluntarily.

One aim of the EPA's mandate to use reformulated gasoline was to reduce the amount of volatile organic compounds (VOCs) entering the ambient atmosphere. VOCs have low boiling points (as well as high vapor pressures); the boiling points of acetone and benzene (both VOCs), for example, are approximately 56 degrees C (133 degrees F) and 80 degrees C (176 degrees F), respectively. VOCs are largely anthropogenic (man-made) in origin. The components making up gasoline are responsible for its relatively high volatility (compared to some other fuels); these components include both normal compounds and those that have been subsequently added. These formulations can be modified to change the volatility. Reformulated gasoline, then, is gasoline that has been altered to lessen the amount of VOCs released to the atmosphere.

The original regulations called for oxygen to be added to fuels at a level of 2 percent (or greater) by weight. Other factors required for gasoline to qualify as reformulated included a limit on the amount of benzene permitted (less than or equal to 1 percent by volume); NO_x emissions that remained stable (or decreased); and an absence of heavy metals (types of toxic pollutants), although the latter requirement could be waived under certain circumstances. Target reductions of VOC emissions (assessed with respect to baseline emissions) also needed to be met. In 2006, the EPA's requirement that oxygenates be added to reformulated gasoline was called off. This permitted producers greater latitude in producing cleaner burning blends that would meet air quality standards.

The United States is not the only country employing vehicle fuel modifications in an effort to reduce the emission of pollutants and improve local and regional air quality. Several European countries have been involved with air quality monitoring and modeling in an effort to generate cleaner environments.

Risks and Consequences Related to Emissions

Health risks to humans can be mitigated by the reformulation of fuels. Various government agencies and institutions plan to enact or have enacted policies designed to decrease the potential damage to humans resulting from exposure to noxious gases emanating from vehicle exhaust. Although

there are up-front costs involved in switching to cleaner, reformulated gasoline, those costs may ultimately lead to greater overall savings, as healthier populations require fewer resources spent on treating health conditions attributed to toxic emissions.

Stratospheric ozone (the variety associated with the ozone hole and sometimes called “good” ozone) provides a protective layer that absorbs harmful ultraviolet (UV) radiation emanating from the sun. In the troposphere, however, ozone acts as a pollutant. High levels of ozone are associated with compromised human health, such as respiratory problems (including asthma and emphysema) and the risk of premature births or low birth-weight babies. Alerts may be issued on days of especially high ozone, suggesting that those with breathing problems, such as asthma, take extra care to avoid unnecessary exposure to ozone-laden air. The health risks associated with tropospheric ozone were an impetus for requiring reformulated gasoline to be sold where ozone levels exceed federal standards.

Smog is another consequence of the deleterious effects caused by traditional gasoline (and which reformulation aims to mitigate). First coined in 1905, the term *smog* is a verbal combination of the words *smoke* and *fog*. Smog originally referred to the thick pollution blanketing urban regions where substantial quantities of coal were burned for both heating homes and industrial activities. Today, though, smog describes a type of air pollution that develops primarily when solar radiation interacts with motor vehicle emissions (although some other emissions, such as those from industry, also contribute to the generation of smog). This is called “photochemical smog.” Photochemical smog is created when solar radiation reacts with VOCs and NO_x ; these are present largely because of the burning of gasoline by motor vehicles. This form of pollution is a particular problem in urban areas where the combination of sunlight and a large volume of motor vehicle traffic is coupled with atmospheric and topographic conditions that inhibit the dispersal of pollutants. Los Angeles (United States) and Mexico City (Mexico) are, for example, synonymous with smog, in part because of the frequent temperature inversions that act as a lid and trap pollutants in a near-surface layer and the cities’ locations in mountain basins that limit the advection (horizontal movement) of air. Reformulated gasoline is designed to reduce the emissions that lead to smog.

The price of E85 fuel (85 percent ethanol and 15 percent gasoline) is lowered during a promotion by the sugarcane ethanol industry in Birmingham, Alabama, April 2010. Ethanol can replace methyl tertiary butyl ether (MTBE) as an oxygen additive to gasoline.

The chemistry behind photochemical smog requires hydrocarbons (in the form of gasoline), solar radiation (reaching the surface as sunlight), and the various nitrogen oxides (NO_x). Nitrogen dioxide forms when NO interacts with atmospheric oxygen (O_2). The oxygen then splits and forms NO and atomic oxygen (O). This occurs after it absorbs solar radiation. Atomic oxygen and O_2 , then, form ozone (O_3) in the presence of sunlight. Simply put, NO and NO_2 react with hydrocarbons (which are present in relatively large numbers due to exhaust from motor vehicles) and form dangerous and volatile compounds. The end result is a brownish orange haze that can aggravate lung conditions, damage trees and other vegetation, and magnify the greenhouse effect.

Although smog results from vehicle exhaust by-products produced during combustion, the problem is exacerbated under certain meteorological conditions. Typically, late spring to early autumn is the time of year when smog difficulties are worse, as conditions are more conducive to smog formation. Temperatures are warmer, which causes the reactions to occur more rapidly (and gasoline to evaporate more

readily). Additionally, the presence of high atmospheric pressure further adds to the problem, since the calm or light wind present inhibits the transfer and dispersal of pollutants to surrounding rural areas by advection. Hence, summer gasoline blends have to meet lower RVP standards. Both summer and winter blends can be reformulated.

Modification and alteration of gasoline requires an analysis of the type and amount of emissions that would result from various reformulations. To do this, those involved in transportation planning and environmental resource management utilize tools called reformulated gasoline predictive models. These models permit investigations into the outcomes of assorted formulations and give regulatory agencies assessments as to the atmospheric impact of different formulas. A series of mathematical equations are utilized to judge the impact of vehicle exhaust on contaminants released to the air. One example of a reformulated gasoline predictive model is the California Reformulated Gasoline Phase Three (CaRFG3) model, which specifically looks at NO_x , CO, vaporized hydrocarbons, benzene, formaldehyde, and acetaldehyde. The implementation of such a predictive model provides some guidance for refiners. For example, they can determine the compliance of a formulation by using the model; emissions must be less than or equal to California standards.

Despite the benefits associated with reformulated gasoline, some disadvantages and criticisms have been noted. One criticism of using the modified fuel is that these altered blends impact the consumer in the form of higher gas prices. Residents of the areas designated by the Clean Air Act (largely concentrated along the eastern seaboard, California, Texas, and Milwaukee–Chicago) do pay higher prices for reformulated gasoline. Although the smog reduction benefits of modified fuels have been shown to mitigate this problem, some critics suggest that modern automobiles are no longer the pollution-spewing machines of the past. They note that newer cars are equipped with emission control technology and that even standard gasoline is now cleaner than it was in the past. Another criticism has been the potential for reduced gas mileage from oxygenated fuels. However, the EPA has found that the reduction is relatively minor, on the order of 2 percent or less; this results in a general decrease of 2 to 4 miles per gallon (0.85 to 1.7 kilometers per

liter). Driving styles, automobile maintenance, and engine type and vehicle size are far greater influences on fuel economy.

Oxygenation: MTBE and Ethanol

Originally, the EPA required that gasoline be oxygenated, as stipulated by the Clean Air Act Amendments of 1990. To ensure that fuel burns more efficiently, gasoline was blended with oxygenating agents.

Various chemical compounds can deliver oxygen to fuel. One such additive is methyl tertiary butyl ether (MTBE), which is a fossil-fuel product. However, MTBE has been linked to environmental contamination and human health problems. A potential carcinogen, MTBE has infiltrated soils and contaminated aquifers as a consequence of being stored in leaking underground storage tanks (USTs). The EPA regulates USTs. Gasoline is held in underground tanks at fuel dispensing stations; should those tanks leak, groundwater supplies become polluted and ingestion of that water poses risks to humans. As the possibility of health problems associated with MTBE became more known, regulators in the United States have called for and implemented phaseouts of the offending chemical. However, studies linking MTBE to health problems have been inconclusive. Nevertheless, California initially began phasing out MTBE as an oxygenator in 2003. Other states have since followed suit.

Ethanol is another common oxygenating compound, particularly in light of the possible cancer ramifications of MTBE. Also referred to as “bio-ethanol” or “pure alcohol,” ethanol is a fuel formulated from plant materials such as corn or sugarcane. Plant sugars and starches are fermented (broken down from carbohydrates to alcohols), which yields a usable fuel form. In the United States, ethanol is largely derived from corn (maize), owing to its vast grain-based agricultural industry; production is concentrated in the Midwest and Plains states. It is sugarcane, however, that provides the primary source of ethanol in Brazil; this is unsurprising, given the tropical climates that permit cane sugar to be grown. Additional plant sources can be used to generate ethanol, such as sugar beets and wheat. Cellulose (as found in wood and grasses) can also be used to generate ethanol, although with more difficulty. Other ethanol-producing countries include China, Canada, and Australia. Collectively, the European Union is the world’s third-largest producer of ethanol

(as of 2011), trailing only the United States and Brazil. Global ethanol production has been increasing, owing to increased demand for fuel and a rising concern over renewable and sustainable resources (and a move toward energy security among producing nations). Global ethanol use is also increasing. Some countries, like Brazil and the United States, have a relatively long history of using ethanol.

In light of the groundwater contamination issues associated with MTBE, the inclusion of ethanol as an oxygenating agent is increasing. Initially, MTBE was preferred over ethanol, as it is easier to move (and thus, cheaper). Ethanol can corrode pipes and (in the United States) must be shipped from the middle of the country (where it is made) to the consuming populations living largely on the east and west coasts. However, ethanol has since gained favor with the decline in the use of MTBE as an oxygen additive to gasoline.

Fuel mixtures are compounds that blend gasoline with ethanol. One such mixture is commonly often referred to as “gasohol”; this describes a mixture that combines gasoline with a small amount of ethanol. In the United States, the term refers to E10, a blend that consists of 10 percent ethanol added to gasoline. This mixture can be utilized without negative consequences in automobile engines (unlike, for example, E85, which is composed of 85 percent ethanol and 15 percent gasoline and requires engines modified to accept this blend). Other mixtures include E5 and E15. The “E” refers to the percentage of ethanol contained in a fuel mixture.

The use of ethanol is not without controversy. There is concern that utilizing corn for fuel rather than food could lead to substantially higher food prices (that is, ethanol shock) and possible unrest. While this would affect poorer countries disproportionately, livestock producers in wealthier countries would also have to pay higher prices for feed. Corn growers can increase production but often not enough meet the demand for both food and fuel. An additional concern is the impact of ethanol production on climate change. Some evidence indicates that a global move toward ethanol would increase greenhouse gas emissions due to land use changes, although more work is warranted.

Conclusion

The employment of reformulated gasoline is one tool in a multipronged approach aimed at reducing

noxious emissions to the atmosphere. Others include vehicle inspections and emissions tests and the promotion of multiple occupant modes of transportation, such as subsidized mass transit and the installation of high occupant vehicle (HOV) lanes in major thoroughfares. However, setting air quality standards like the NAAQS that can be met (at least partly) by using reformulated gasoline may be more likely to result in cleaner atmospheric environments where automobiles are an important part of the local culture.

Gasoline Engines

Gasoline engines have dominated the automobile industry since the popularity of Henry Ford’s mass-produced Model T car in the early 1920s. In the early decades of the 21st century, the gasoline engine is losing ground to more innovative methods of propulsion, although it still is the dominant engine fuel. In 1876, German inventors built the first gasoline-fueled, four-stroke cycle engine, and in 1886 Karl

Benz introduced the first commercially produced motor vehicle with an internal combustion engine. By the 1890s, automobile entrepreneurs had developed motor cars to their modern designs so successfully that the principles of the ordinary automobile gasoline engine have remained the same since then. In 1900, Ransom E. Olds stopped producing steam-driven cars and introduced gasoline-fueled vehicles, and in 1908, when Henry Ford put his affordable mass-produced Model T Ford on the market, the gasoline-powered internal combustion vehicle quickly became standard. Mass production of these cars put vehicles on the market that were modestly priced, easy to maintain, fast and powerful, capable of long-distance travel, and powered by gasoline—a cheap, plentiful, and widely available energy source.

In the 20th century, demand for gasoline spurred petroleum industry growth. Consumption of gasoline soared from a 1919 low of less than 3 billion gallons to approximately 15 billion gallons in 1929, 46.5 billion gallons in 1955, and more than 135 billion gallons in 2002. According to the U.S. Energy Information Administration, in 2011, the United States consumed about 134 billion gallons of gasoline, about 6 percent less than the record high of about 142.38 billion gallons consumed in 2007. In 2013, automobiles were responsible for almost 90 percent of the energy consumed for travel in the United States.

Gasoline Engines as Power Trains

In the mid-20th century automobile entrepreneurs introduced the turbine-powered car, as well as the blanket term *power train* to identify the propulsion systems that move cars and trucks. Power trains include gas engines, diesel engines, battery-powered electric motors, and electric motors powered by hydrogen fuel cells. In 2013, engines were not confined to gas or diesel. Clean-burning engine options proliferated, ranging from domestically produced alternative fuels like biodiesel, ethanol, compressed natural gas, liquefied natural gas, and propane gas. The gasoline engine, which has been widely used for more than a century, is still the undisputed number one power train. Ninety-nine percent of all automobile manufacturers devote enormous research and development budgets to gasoline engines to keep classical gasoline engine technology relevant and viable by enhancing its efficiency.

Many factors contribute to make the gasoline engine the top power train. The tooling, materials, assembly techniques, maintenance, and repair procedures in producing gasoline are conventional and widely understood worldwide. The four-stroke piston-driven gas engine is the basic model used in auto shop and mechanic training classes and the model that students study before moving on to other propulsion methods.

Although gasoline engines contain complex moving parts, their parts are flexible enough to allow their designers freedom to modify them as needed. Gasoline-engine performance may be adjusted for horsepower or torque, more or less fuel economy, and more performance in the lower, middle, or top of the engine's range. This flexibility makes gasoline engines viable in small, medium, or large cars, minivans, crossovers, sport utility vehicles (SUVs), and pickup trucks. Gasoline is easy to find, access, and distribute, with no unusual handling specifications, and it is an energy-dense fuel, with a single gallon containing 33.7 kilowatt hours of chemical energy.

In addition to overwhelming positive factors, the gasoline-powered engine has its drawbacks as well. Practically speaking, the piston-driven gas engine is thermodynamically inefficient. An excessively optimized engine might turn nearly 40 percent of the energy in a gallon of gas into useful propulsion. For modern gas engines, anything above 30 percent is considered acceptable; the rest of the energy is lost as friction and heat.

Gasoline engines need routine maintenance. Lubricating oil needs to be changed, seals need to be repaired, filters need to be swapped or cleaned, and rubber parts and ancillary belts in engines need to be replaced. Because it is produced from crude oil, gasoline is a volatile commodity, with fluctuating prices. In 2011, the United States imported about 45 percent of its petroleum, with Canada and Saudi Arabia being the biggest suppliers. The U.S. Environmental Protection Agency reported that American dependency on oil imports has been falling since 2005.

Ethanol and Gasoline Engines as Power Trains

Ethanol fuels contain less energy per gallon than gasoline, but they are substitutable. The most popular ethanol fuel is E85, which stands for 85 percent ethanol and 15 percent gasoline. Ethanol is easier

to find in the Midwest because of regional proximity to its fuel source—corn and assorted grains, primarily—but farm waste may also be an ingredient. The federal Renewable Fuel Standard program guarantees ethanol must be blended into standard gasoline, with formulas including E5 (5 percent ethanol and 95 percent gas), and E10 (10 percent ethanol and 90 percent gas, and E15 (15 percent ethanol and 85 percent gas). E0 ethanol is 100 percent gas. Ethanol might help reduce America's dependence on foreign oil.

On the negative side of the equation, a unit of ethanol contains less specific energy than a unit of gasoline, and the alcohol in ethanol can damage the engines and fuel systems of older vehicles if the ethanol mix is powerful enough. Modern vehicles are designed to tolerate at least up to E10 blends satisfactorily, and vehicles accepting E85 are normally designated as flex-fuel ready. When running on E85 ethanol, an engine is generally downgraded in its Environmental Protection Agency (EPA) fuel economy ratings because it produces less energy per gallon.

The Environmental Impact of the Gasoline Engine

After Henry Ford and other entrepreneurs mass-produced the automobile, gasoline engines and increased fossil fuel production poured toxic chemicals into the atmosphere. Adding many thousands of cars on the road after World War II increased the spread of air pollution, added more and newer pollutants, and threatened many major cities with smog, inversions, and polluted water.

Oil production and gasoline, one of its significant by-products, have had the most significant environmental consequences. The technical limits of the gasoline engine and the massive scale of automobile production have created devastating pollution. In 1955, Congress passed the National Air Pollution Control Act to stimulate air pollution research, but the role of automobile emissions and the gasoline engine in the pollution story took several years to evaluate, and it is still being addressed in the 21st century.

The various components of the gasoline engine, individually or together, are a health hazard to people and the environment. Auto emissions can cause headaches and contribute to lung cancer, emphysema, and respiratory and cardiovascular problems.

They modify weather conditions, damage vegetation, and erode rubber, textiles, dyes, and other materials.

In 1923, gasoline makers introduced another toxic substance, tetraethyl lead, as a gasoline additive, which added another threat to human health. During the decades of the 1960s, 1970s, and 1980s, thousands of automobiles burned huge quantities of gasoline, depositing lead on the soil to be tracked into houses across America. Infants and children ingested the lead, which contributed to nervous system problems, including hyperactivity and hearing loss. Lead does not break down once it is released into the air, and between the 1920s and 1986 when it was finally phased out as a gasoline additive, gasoline engines emitted 7 million tons of lead across the United States.

Oil Companies and Gas for Gasoline Engines

Petroleum products are vital to automobile manufacturing and use, so the environmental effects of drilling, transporting, and refining oil play an important role in the equation between the automobile and the environment. Companies that drilled for and produced oil did not match their success with foresight and restraint in producing and marketing it. Greed, waste, and disregard for conservation measures dominated the oil industry, although in the early 20th century some states passed conservation laws in an attempt to cope with the more harmful oil industry practices. While state and federal authorities were concerned with potentially running out of oil, they ignored oil field waste, pollution, and other environmental problems. Congress attempted to address oil field problems and pollution, but oil-producing states vigorously resisted. Congress did successfully pass the Oil Pollution Act of 1924, which attempted to curb oil discharges from shore plants and ships. The act featured weak enforcement provisions and dealt only with oil-burning vessels dumping fuel at sea.

After World War II, states and the federal government attempted to deal more successfully with gasoline and oil production pollution. Beginning in 1957, small imported cars began to invade the U.S. market while American automobile manufacturers concentrated on producing bigger vehicles with larger engines. GM, Ford, and Chrysler, the Big Three American manufacturers, did not believe a large market existed for small cars, and as long

as gasoline remained abundant and cheap, they continued to produce larger, more powerful automobiles, basing their long-range planning on larger gasoline engines. High-compression engines produced greater horsepower and quicker acceleration for highway travel, and automatic transmissions made driving easier. The side effects of more cars, bigger engines, and automatic transmissions were loss of fuel economy and increased air pollution.

With the exception of California, which led the way in emissions control legislation, the states combated automobile emissions slowly. The 1963 Clean Air Act for the first time gave the federal government limited enforcement power over interstate pollution. The Motor Vehicle Air Pollution Act of 1965 produced national standards comparable to California law, and in 1967 the federal government passed the Air Quality Act, the first piece of federal legislation designed to control lead emissions. By 1966, automobiles and other motor vehicles contributed more than 60 percent of the pollutants in the atmosphere across America, and in 1968 hydrocarbon emissions came under federal jurisdiction.

By the 1960s, some states and the federal government argued persuasively that further pollution by gasoline engines threatened the economic development of the United States. World attention turned to the problem in March 1967 when the supertanker *Torrey Canyon* ran aground off the English coast, spilling most of its 120,000 tons of crude oil into the sea.

On January 28, 1969, a Union Oil well exploded off the Santa Barbara coast in California, ultimately leaking 235,000 gallons of oil into the ocean and further underscoring the need for environmental protection legislation. Congress tightened leasing regulations and pronounced offshore operators liable for cleaning spills. The dramatic events of the Union Oil spill helped encourage the growth of the modern environmental movement and pressured the federal government to pass the 1969 omnibus environmental law, the National Environmental Policy Act (NEPA), but even after it passed, many environmentalists believed that the law had little substance.

In the 1970s, the major environmental battle affecting gasoline engines focused on the Alaska pipeline. In 1968, Atlantic Richfield (ARCO) struck a massive oil field estimated at 4.8 billion barrels

at Prudhoe Bay, Alaska, and soon supporters were clamoring for a pipeline to run 800 miles from Prudhoe Bay south to the port of Valdez. Environmentalists opposed the pipeline on the grounds that it would destroy pristine wilderness, but the 1973 oil embargo undermined their position. In 1973, Congress passed the Trans-Alaska Pipeline Authorization Act and the first oil flowed through the pipeline in 1976. The oil tanker *Exxon Valdez* collided with a reef in Prince William Sound in 1989, splitting open and discharging thousands of gallons of crude oil into Alaska's coastal waters. The accident surpassed the Santa Barbara spill and fueled the continuing debate over the pipeline and other exploitation of Alaskan oil.

The concerns about environmentally harmful accidents, dissatisfaction with existing federal laws, and indifferent state enforcement of laws protecting the environment provided the impetus for the 1970 Clean Air Act Amendments. The most stringent air pollution laws ever passed in the United States, the Clean Air Act Amendments dealt with auto emissions and stationary pollution sources. An amendment to the 1970 Clean Air Act provided further reductions in emissions and authorized the Environmental Protection Agency (EPA) to set emissions standards for new automobiles and other motor vehicles.

A reluctant automobile industry and the energy crisis of the early 1970s created a difficult climate for the Clean Air Act Amendments. The 1970s amendments provided that the EPA could grant a one-year delay in meeting the more stringent environmental standards if the automobile companies made the effort to meet the new standards. Some critics questioned whether the automobile companies had acted in good faith because they used the research and development work of independent companies instead of using their own laboratories and personnel for emissions control technology.

The Clean Air Act Amendments of 1990 substantially revised the 1970 and 1977 acts, with two of the 11 titles particularly focused on transportation. The acts involved a plan to classify cities according to the severity of their emissions problems and how well they met the earlier standards. The new law also established more stringent emissions standards for automobiles and a few trucks for model years 1996–2003. California and some other states were already attempting to

tighten exhaust standards, which the new law supported, but the administration of George H. W. Bush resisted more stringent exhaust standards like California's 1996 Phase II. Instead, the Bush administration promoted new fuels like reformulated gasoline, methanol, ethanol, and natural gas, and the introduction of clean cars in cities with the worst ozone problems. The oil and automobile industries opposed the clean fuels and clean car strategies, but they accepted a diluted version of the law instead of being forced to accept laws similar to California's Phase II exhaust standards.

The automobile and oil industries continued to resist tougher standards for clean air, while the public endorsed clean air but resisted carrying the burden of responsibility through higher costs and reduced automobile performance. Americans still cherish the automobile powered by a gasoline engine.

Geographic Information Systems in Transportation

Because of the spatial separation of resources and services between where they are located and where they are needed, it is necessary to move goods, people, and information among different locations in order to meet various needs in daily life. Transportation therefore is an essential part of human society and is geographical in nature, in that it must deal with not only locations but also interactions among different places. Geographic information systems (GIS), which are computer systems for managing, analyzing, and visualizing geographically referenced data, can offer a useful environment to integrate spatial and nonspatial transportation data in support of transportation planning, operation, maintenance, and evaluation. Such use of geographic information systems to address various transportation-related issues is known as geographic information systems in transportation (GIS-T).

This map of New Hampshire's Route 153 uses geographic information system data from the U.S. Census Bureau, the National Highway Planning Network, and the National Atlas.

Transportation was among the earliest fields to make use of geographic information systems. GIS can be thought of as a computer database that consists of different map layers (for example, land use map layer, transportation network map layer, population census tract map layer, traffic analysis zone (TAZ) map layer, among others) showing various characteristics at different locations in a study area. Query functions can then be used in GIS (for example, what is the land use type at a particular location? or which road segments have an annual average daily traffic above a specific level?) to answer questions.

In addition, GIS offer a set of spatial analysis functions to answer questions related to locations and spatial relationships. For example, a half-mile buffer zone can first be generated around each subway station and then the buffer zones overlaid with a land use map layer to derive land use characteristics around individual subway stations. The shortest path function can also be used to find the best route for traveling from one location to another location on a transportation network. Some basic

GIS-T analysis functions are available to the general public through Internet applications, such as Google Maps. Another advantage of using GIS in transportation is the ability to visualize the data and analysis results in a map format. Since GIS include a database of spatial and attribute data along with a set of mapping functions, they offer useful mapping capabilities beyond what computer-aided drafting (CAD) software products normally deliver. Many transportation agencies therefore have used GIS as the main software environment to manage their data for mapping and analysis purposes.

Evolution of GIS-T

Transportation and GIS have developed as two separate fields with their own specific focuses. Transportation professionals focus on the best ways of meeting the needs of transportation planning, management, operation, maintenance, and evaluation, while the GIS field attempts to address the needs of managing, analyzing, and visualizing spatial data in support of a wide range of application fields. It therefore should not be assumed that all transportation problems can be properly addressed in a GIS environment. In fact, GIS in transportation has evolved over time and will continue to evolve as new transportation challenges surface and new technologies become available.

Because transportation serves as an important map layer in many GIS applications ranging from urban to economic to environmental issues, the DIME and TIGER files showing streets and highways throughout the United States (released by the U.S. Census Bureau in 1980 and in 1990, respectively) provided critical momentum to facilitate GIS applications in transportation and other related fields. The American Association of State Highway and Transportation Officials (AASHTO) started its GIS for Transportation Symposium in 1987, and GIS activities have grown in both the transportation research and application communities since the 1990s. Michael Goodchild characterizes the GIS-T evolution into three stages: the map view, the navigation view, and the behavioral view. The map view takes a static approach with an emphasis on transportation data inventory and description. The navigational view focuses on the data representation of network connectivity and planar topology along with time-dependent attribute data. The behavioral view employs Torsten Hägerstrand's time geography concepts of dynamic

movements of individual trajectories in a space-and-time context.

With the modern location-aware technologies, such as the Global Positioning System (GPS), Wi-Fi positioning system, radio frequency identification (RFID), and mobile phone tracking, it has become feasible and affordable to collect large volumes of tracking data of individual vehicles, shipments, and/or people. Coupled with rapid advancements in information and communication technologies (for example, the Internet and mobile phones), important changes have been observed in spatial and temporal patterns of both human and freight movements. For example, the just-in-time (JIT) practice introduces important changes to where and when products are manufactured, stored, and delivered.

Various real-time monitoring and communication devices installed for intelligent transportation systems (ITS) provide continuous data streams that are used to control traffic flows, respond to emergency situations, inform the public, and/or conduct studies to improve transportation planning and design tasks. Moreover, due to the increasing activities carried out on the Internet, such as e-shopping, e-commerce, e-government, online education, and online social networks, along with the increasing use of online applications of smartphones and other mobile devices, human activities and interactions have exhibited changing spatial and temporal patterns. For example, a customer now can place an order at Amazon.com any time of the day and the item is shipped to the customer's location instead of the customer having to make a trip to a retail store. These changes have important implications for travel demands and traffic patterns.

Since GIS traditionally focus on spatial data represented as static snapshot map layers, such dynamic and mobile data sets present major challenges to GIS-T, which now must be able to effectively and efficiently manage the data in order to provide insights on movements, interactions, changes, and processes in a spatial and temporal context. It can therefore be expected that GIS-T will evolve toward an environment that can better represent, analyze, and visualize dynamic and mobile data in addition to the conventional static data.

What Is Special About GIS-T?

Data representation is the core of GIS. For GIS-T, it is critical to properly represent different types

of transportation data, such as transportation networks (for example, highway network, rail network, transit network), transportation features (for example, traffic sign, median, bus stop), and traffic data (for example, traffic volume, traffic accident, bus schedule). A transportation network is often represented as a set of links interconnected at a set of nodes. Transportation features can be represented as stand-alone GIS map layers, such as a point map layer showing the locations of bus stops or a line map layer showing the locations of medians.

A disadvantage of representing transportation features in separate GIS map layers is that they are not directly associated with their corresponding transportation networks. The transportation community therefore has developed linear referencing systems (LRS) to record the locations of transportation data along a linear transportation route. For example, one can record the location of an on/off ramp or an accident at a specific milepost (for example, milepost 373) on an interstate highway (for example, I-40) in Tennessee. This type of one-dimensional measurement system is different from the conventional two-dimensional Cartesian coordinate system used in GIS. This has prompted the GIS-T to develop a dynamic segmentation data model to accommodate linear referencing data.

Transportation data also frequently deal with traffic flows between a set of origins and a set of destinations, which are represented as origin–destination (OD) matrices. GIS, however, are mostly based on a relational database management system that cannot properly handle OD matrix data and matrix operations. A comprehensive GIS-T therefore should support multiple data models that are required by different transportation applications.

Another requirement of GIS-T is to support various transportation analysis needs. Transportation agencies are responsible for a wide range of tasks, such as transportation system management, infrastructure planning and design, travel demand analysis, transit service, and environmental impact assessment, among others. Each of these tasks has its specific data and analysis needs. For example, traffic engineers may need to look at the design of individual traffic lanes whereas transportation planners often represent roads as centerlines. Also, most network analysis functions, such as the shortest path finding algorithm, require only topological

relationships among the links and nodes in a network and do not need to know their specific locations or exact geometries.

Furthermore, there exist many kinds of transportation analysis methods and models, including spatial interaction models, routing problems, network flow models, facility location problems, and environmental assessment models. It is necessary to integrate these methods and models with GIS in order to support various GIS-T applications. However, many of these analysis functions are not available in general-purpose commercial GIS software products. It is a common practice to couple transportation analysis software with GIS software through some forms of data exchange to take advantage of both systems.

GIS-T to Meet Transportation Challenges

Although human mobility has improved significantly due to technological advancements over time, there exist a number of major challenges in transportation. For example, it is not sustainable to rely on fossil fuels as the main energy source for transportation due to their nonrenewable nature and contributions to air pollution and climate change. Traffic congestion in urban areas is getting worse. Transportation infrastructure is aging and governments often do not have adequate finances to properly maintain or replace them. Safer transportation systems are needed to reduce traffic fatalities and accidents. In addition, major natural disasters and terrorist attacks in recent years have revealed the weaknesses in U.S. transportation systems in terms of emergency response and system security.

How can GIS-T be used to help address these transportation challenges? This is what some researchers are focusing on to demonstrate the relevance and value of GIS-T. For example, GIS could be used to assess the suitability of adopting alternative energy sources (such as solar, wind, or biofuel) in different regions of the world. Modern tracking technologies could also be used to gain insights on human mobility patterns and design transportation systems and services that would better meet their spatial and temporal mobility needs. Furthermore, GIS could help us prepare evacuation plans in response to natural disasters or emergency situations. However, it should be kept in mind that GIS per se cannot solve these transportation challenges. It requires people with application domain

knowledge working with GIS professionals to tackle these transportation challenges. This is what GIS-T is—an integration of transportation with geographic information systems that can benefit and advance both fields.

Global Economic Centers

When studying transportation, it is critical to know where people are going. One way to predict where people are going, or at least one stop on their trip, is to identify the great global cities that act as the world's economic and cultural activity centers. Current global financial centers include London, New York City, and Hong Kong. In addition to being the financial centers, these great cities are also the centers for culture and learning. When looking at these cities on a map, one cannot help but notice certain trends. Most obviously, the current financial centers tend to be capital cities of former colonial powers or regional hubs for those colonial powers. Sociologists have studied issues surrounding these trends by examining theories surrounding colonialism and economic dependency. Three up-and-coming global cities are the Asian cities Beijing, Shanghai, and Taipei. Up-and-coming cities tend to be located in Asia, and many of them tend to have a past or present relationship with China.

Current Global Powers

Financial success is one of the most basic and commonly used metrics for understanding the prosperity of a city. For this reason, the financial analyses by credible organizations of global cities can be used to compare them in terms of not only finances but also culture, travel, and infrastructure. The world's global financial centers have been identified by surveys of influential globalist organizations, such as the World Bank. These studies compare the people, business environment, market access, infrastructure, and general competitiveness of these cities. By these metrics, London, New York, and Hong Kong have been identified as the world's three most influential cities.

London was first settled as part of the Roman colony of Britannia and has been a major settlement for over two millennia. London is by most every measure the greatest financial city in the world. As the capital of the United Kingdom, it was the birthplace of the Industrial Revolution, center of the former British Empire, and has been a world capital ever since. London is the largest urban zone in both the United Kingdom and the European Union. In addition to being an economic and political capital, London is also a world cultural capital, containing four world heritage sites. Additionally, it is a tourist, transport, education, and media center; London is truly a world capital in every sense of the word.

New York City is the most populous city in the United States. The city hosts arguably the most advanced commuter system in the United States, and possibly the world. New York's transit system integrates advanced subway, bus, and highway systems. While New York is not a political capital in the proper sense of the word, it is the home of the United Nations as well as a major finance and culture center. In terms of long-distance travel, most surveys show New York is the destination of choice for foreign visitors to the United States and the gateway for immigration for the East Coast.

Hong Kong entered the global scene when it became a British colony after the First Opium War in 1842. Hong Kong is located within (what is today) the Special Administrative Regions (SAR) of the People's Republic of China. Hong Kong became part of China in 1997. During this transition, the city-state was able to maintain a degree of sovereignty due in part to its financial success.

This eastern city with its expansive skyline and deep natural harbor is also one of the most densely populated spots in the world. Hong Kong boasts a major capitalist economy with low taxation rates and its own currency, which remains independent of that of the People's Republic of China.

Emerging Global Activity Centers

In this ever-changing world, it would be both arrogant and foolish to discount those cities that are not yet global capitals but soon will be. The majority of these up-and-coming cities are in Asia. Three examples of up-and-coming global cities are Beijing, Shanghai, and Taipei.

Beijing is an ancient city that, aside from its recent financial prosperity, is known for its palaces, temples, gardens, tombs, walls, and gates. Once known in the Western world as Peking, Beijing is the capital of the People's Republic of China. Beijing is located in northern China and is the second largest Chinese city by urban population. As the capital, Beijing is China's political, cultural, and educational center. Due in part to its importance to the national character, Beijing serves as the major hub for the national highway, expressway, railway, and high-speed rail networks. In fact, Beijing Capital International Airport is the second busiest in the world by passenger traffic.

Like Beijing, Shanghai is also a popular tourist center due to its historic landmarks and cultural significance for the Chinese people. Shanghai is the largest city by population in the People's Republic of China. Shanghai is a city of global influence in commerce, culture, finance, media, technology, and transportation. Shanghai has been a major administrative, shipping, and trading center in the Eastern world for centuries. With the rise of China as a global power, Shanghai is quickly becoming a major financial center on a global scale, boasting the busiest container port in the world.

Taipei is the capital of Taiwan (also known as the Republic of China). Taipei became the home of the exiled ruling government after being defeated by the Communists in the Chinese civil war. As the capital of Taiwan, this port city is the political, economic, and cultural center of that small nation. In terms of transportation, Taipei is a hub for railways, high-speed rail, highways, airports, and bus lines. These transit lines connect Taipei with all parts of the island.

Social and Spatial Divisions

A little bit of global awareness will tell you that economic inequality around the world is massive. For this reason, economic activity centers are not evenly distributed around the world. A significant portion of these global inequalities can be attributed to the legacy of colonialism. During this system, powerful European nations dominated the rest of the world through exploitative trade relationships. Though existing remnants of these relationships do not help dissipate global inequality, sociologists contend that much of the world's existing inequality can be accounted for by dependency theory.

Dependency theorists contend that certain nations continue to grow by exploiting other nations for the benefit of the exploiters. This theory is given credence by the growing share of global resources accumulating in certain countries while others suffer. Dependency theorists divide the world into three categories: core nations, semiperiphery nations, and periphery nations. Core nations are those nations that have maintained power after giving up a degree of it after the colonial area. They tend to have service- or technology-based economies. Core nations also make a great deal of profit from abstract financial products that rely on the production of periphery and semiperiphery nations.

Examples of core nations include Canada, the United States, France, Japan, and the United Kingdom. Semiperiphery nations are those countries that maintain a degree of independence from the core but are still not at the center of world commerce. Examples of semiperiphery nations include the People's Republic of China, India, Ireland, and Mexico. Periphery nations are many of those that were once referred to as the "third world." They possess underdeveloped economies and infrastructure. Often they derive the majority of national income from the export of natural resources, with little industrial or technology economy. Examples of periphery nations include Afghanistan, Bolivia, Chad, the Philippines, and Vietnam.

Globalization

Globalization refers to the factors that interconnect various locations of the world in ways that make the world more accessible for business, travel, and cultural exchange. Globalization is often thought of as making the world smaller in terms of reducing the difficulty of interacting with distant peoples, economies, and cultures. Factors that have led to globalization include the increasing ease and relative decrease in the cost of travel, access to low-cost and effective communication, the strengthening of once-weak economies, growth of multinational corporations, ease of monetary transfer through the international banking system, and the ability of the transport industry to move goods in an increasingly efficient, expedient, and safe manner.

Another crucial factor is the increased trade between nations. This is because of decreased

tensions between some nations and trade agreements entered into by many nations. The use of cheap labor in some countries to produce the goods that will be consumed in nations with more expensive labor costs is at the heart of the nexus between globalization and transportation.

One of the major impacts of globalization has been the rapid growth of international trade. Japanese cars are now often made in America. U.S. carmakers import many components for their cars from other nations. These American carmakers are even assembling their cars in other countries, for example, Ford and its Mexican assembly plants. Countless American companies like Walmart contract with companies in countries with a cheap labor supply and import goods made abroad to be sold in the United States.

In countries like Vietnam, Indonesia, China, and even Haiti, residents are provided work to make products that are shipped around the world. With the emphasis of organizations like the World Trade Organization (WTO) and the General Agreement on Trade and Tariff (GATT), trade among many of the countries in the world has dramatically increased. This increase in international exchange is made possible, in large part, by the modern transportation system.

Probably the most dramatic development in transportation of goods as it relates to globalization was the advent of container shipping. Containers are metal boxes that closely resemble the trailer portion of a tractor-trailer truck. Prior to the use of containers, goods had to be loaded on trucks or trains, transported to a port, unloaded, and then reloaded onto the ship. This process had to be duplicated in reverse on the receiving end. The manual labor of longshoremen at the docks was intense and added greatly to the cost of shipping.

Using containers, the manufacturer is able to load a container at the point of manufacture. The container is then loaded onto trucks or trains, and sometimes on barges, and taken to the port, where it is quickly loaded by crane onto a container ship. On the receiving end, the process is just as efficient. Whereas before the use of container shipping a freighter might be in port for multiple days to be unloaded by longshoremen, today a container ship can be offloaded in just a few hours. One of the factors necessary for efficient trade between countries is the speed of transport, and

container shipping has greatly reduced the time for shipping goods.

Intermodalism

With globalization has come a dependence on intermodalism. Intermodalism is the use of different modes of transport without having to unload and reload the goods when a different mode is to be used. Containers can be taken by truck to a rail yard and quickly loaded onto a flatcar. Trucks or trains can deliver the containers to a port where they can efficiently be loaded onto a ship. Without intermodalism the rapid growth in trade would have been hampered by the lengthy and expensive process of loading and reloading the goods each time the mode of transport was changed.

While the major economies of the world have been able to build the port facilities necessary to handle container ships, there are poor countries that have not been able to provide the ports that are compatible with container ships. These countries find themselves at a major competitive disadvantage.

The interdependence of countries' transportation infrastructures has been made very evident in a globalized world. Brazil has become a major grain exporter to the world. As such, it becomes a competitor with grain producers in the grain belt of the United States. Because Brazil is on the eastern coast of South America and because that coast extends out into the Atlantic, Brazil may have a competitive advantage in getting grain to the markets across the Atlantic. Grain from the United States has to move down the Mississippi River and be put through a number of locks that are limited in size. This forces the shippers to move their barges through the locks a few at a time. When a completed tow is through the locks, they are tied together again and taken down the river to the Gulf of Mexico and then on to market. For this reason, some are pushing the U.S. Army Corps of Engineers to build new and larger locks that will make it possible for multiple barges to get through the locks more quickly.

The Panama Canal is now in the process of being enlarged to make it possible for more ships and larger ships to go through the canal. Larger ships have been forced to take other routes. When the expansion is completed, larger ships will be bringing goods to the United States. The problem is that

many ports are not equipped to handle the larger ships. Also, some shipping channels, like the Mississippi River, will need deeper dredging to accommodate the ships that will have a deeper draft.

Air transport has become cheaper and more available as planes have grown in size and are being made more fuel efficient. Perishable goods, like cut flowers, can now be supplied to the world market by plane. There has also been a growth in the shipment of packages and goods by international shippers who use aircraft for their long-distance shipping. Companies like UPS and FedEx now have international routes.

As environmental concerns receive more attention from the world community, the transport industry has had to give much more attention as well. After the environmental damage done by oil tankers that sank or had a breach in their hull, shipbuilders were asked to provide ships that were less likely to do damage. Building ships with double hulls was one of the solutions.

The role of fossil fuel is an increasingly important issue in transport and globalization. China is importing more oil. This has led to an increase in the cost of fuel. The United States is looking for alternative fuel sources at the same time that it increases its domestic crude oil and natural gas production. These factors have an impact on where in the world oil has to be shipped.

GPS

The movement of goods, services, and people across the United States and global transportation infrastructure have evolved tremendously over the past two decades, due in part to technological advancements and the commercial and civilian availability of the Global Positioning System (GPS).

The GPS, a U.S.-owned utility, is a dual-use, satellite-based system that provides accurate positioning, navigation, and timing services to users around the world. While GPS was at one time only used by the U.S. military and defense support agencies, free and open access to GPS data by the civilian sector and commercial industry has significantly changed the landscape of the global information and transportation infrastructure—improving the way people and goods are moved around the globe.

Development of the GPS began in 1973 under the U.S. Department of Defense to support critical military operations but did not gain full operational capability until early 1995. In 1996, President Bill Clinton established GPS as a dual-use system to support both U.S. military and civilian applications, signing the U.S. Global Positioning System Policy on March 29 of that year.

The policy established the GPS as a national asset and opened its use to the civilian and commercial sectors. One of the major goals of this policy was to promote the safety and efficiency of the U.S. transportation sector, influencing how the transportation infrastructure was developed and used.

In 1998, Vice President Al Gore announced a series of modernization efforts to improve the performance of GPS data provided to civilians and commercial industry partners, including increasing the availability and responsiveness of the system. By 2000, President Clinton, with authorization from the U.S. Congress, announced the decision to stop degrading the accuracy of GPS data for civilian use, making the location data up to 10 times more accurate.

This measure signaled the United States' last formal policy step in the modernization initiative, thereby ensuring private-sector investment into GPS services and technological advancements and encouraging civil, scientific, and commercial users' integration of GPS data into their applications for use by the public.

System Operation

The system is owned and operated by the U.S. government, with the Interagency GPS Executive Board overseeing the system's overall management, including maintaining and improving upon the system's performance and accuracy.

The location and timing data for the GPS is provided by a constellation of satellites and respective navigation payloads that produce GPS signals. These are linked to GPS ground stations and command and control facilities operated by the U.S. Department of Defense and the Standard Positioning Service (SPS), which services the civilian and commercial sectors.

The GPS system consists of space and control segments, maintained and operated by the U.S. Air Force, and a user segment. The space segment represents a constellation of 24 satellites more than 10,000 nautical miles above the Earth, each orbiting the planet twice during a 24-hour period. The control segment consists of monitoring stations that update and correct errors in navigation data received from the satellites, and the user segment is represented by receivers that pick up these signals from the orbiting satellites.

Four satellites are used at any one time to identify the precise position of a GPS receiver on Earth, with the first three satellites narrowing the possible range of locations and the fourth confirming the precise location of the receiver, which can range in accuracy from 3 to 15 meters, depending on the device. The information provided by the GPS includes longitude, latitude, altitude, and time; each satellite contains multiple atomic clocks that contribute precise time data to GPS signals picked up and decoded by GPS receivers. Many economic activities, such as communication and financial networks and electrical power grids, rely on GPS for this precise timing information in order to synchronize operations and improve efficiencies. The free availability of GPS has enabled cost savings for many companies that depend on GPS to provide this capability.

In addition to the current GPS civilian service, the United States has been working to implement additional civilian signals, the first of which was launched in 2005. The access to these new signals by the civilian sector will result in increased accuracy, availability, and integrity for all users, as well as increased robustness for safety of navigation (both air and maritime) and increased interoperability

The Air Force launches the fourth of a series of eight GPS IIR modernized satellites into space from Cape Canaveral in Florida on a Delta II rocket, October 17, 2007. The U.S. Air Force provides at least 24 satellites for GPS at most times.

between GPS and international satellite navigation systems. These signals are being phased in incrementally by the U.S. Air Force as it launches new GPS satellites to replace aging assets. The U.S. Commerce Department estimates that the additional signals for civilian use will result in more than \$5.5 billion in economic benefit by 2030.

Because of the amplified use of GPS worldwide, the United States has seen an increase in the impact of GPS on the following areas: aviation, agriculture, environmental restoration and protection, marine navigation, public safety and disaster relief, rail transportation, civilian recreational uses, roads and highways, space endeavors, surveying and mapping, and timing.

Civilian Use

With the expansion of GPS to the civilian and commercial sectors, demand for equipment and capabilities to access the data also have grown. This growing demand supported a response by the U.S. commercial industry to develop personal-use GPS data-receiving equipment and services aimed at providing enhanced GPS services to consumers. This free and open access led to a plethora of technological applications affecting every aspect of modern life. GPS data-receiving units and devices can now be found in cars, cell phones, wristwatches, shipping containers, and even ATMs.

Additionally, industry has seen direct economic impacts through established cost savings and boosts to productivity because of the availability of GPS data. Market research suggests that annual GPS data-receiving equipment revenues related to commercial, consumer, and military customer bases in North America alone have averaged more than \$33 billion during a five-year period (2005–10).

When installed in a car for personal use, a GPS data-receiving unit provides information to the driver about the car's location and the best travel routes to any given destination. To do this, GPS information is combined with a geographic information system (GIS), which helps align the precise geographic coordinates with known digital maps already uploaded to a GPS data-receiving device. By providing a visual, map-based format, a driver can decide on an optimum route and can adjust that route according to traffic conditions and preferences; the device continually recalculates the route based on the driver's changing position and updates and displays the information required by the driver. Many devices now include additional details, such as services along the chosen route and narratives to guide drivers through directions to their destination.

GPS data receivers can also track the distance a vehicle travels per trip and record the associated driving activity, such as destinations and routes taken. Because of these advantages, GPS technology is increasing in popularity among vehicle owners, with many car manufacturers opting to provide standard GPS data-receiving functionality in newer product lines.

Despite these advantages, some problems with blocked reception still exist, for example in landscape conditions such as mountains, high buildings, tunnels, urban canyons, or thick-branched

trees. However, technology that utilizes GPS data is advancing very quickly, and newer devices are being developed every year to correct problems and focus on improved accuracy, better reception, and even more user-friendly features.

Recent safety features associated with GPS have also significantly contributed to saving lives by speeding the delivery of emergency services to disabled vehicles and their passengers. This contribution to consumer and travel safety has become an increased priority for the automobile industry, as focus has shifted from meeting basic transportation needs to designing and implementing features that make a vehicle safer to operate, including location services utilizing GPS data to assist emergency services with locating a vehicle in the case of an accident.

The transportation industry is currently studying additional ways to use GPS to help drivers by providing warnings of potential critical situations, such as traffic violations or crashes. Additional research is being conducted to examine the potential for minimal vehicle control when there is a clear need for action, such as the predeployment of air bags, and GPS is vital to the success of this research.

The continuous modernization of GPS and receiving devices has transformed the way typical users travel. The capabilities offered to these users have increased travel options for many, while also reducing issues and improving efficiencies. With this continuous modernization, one can expect even more effective systems for crash prevention, distress alerts and position notification, electronic mapping, and in-vehicle navigation with audible instructions.

Roads, Highways, and Mass Transit

The availability and accuracy of GPS data offers increased efficiencies and safety for vehicles using highways, streets, and mass transit systems. Many of the problems associated with the routing and dispatch of commercial vehicles is significantly reduced or eliminated with the help of GPS data. This is also true for the management of mass transit systems, road maintenance crews, and emergency vehicles.

The U.S. government estimates that delays from traffic congestion on the nation's highway and transit systems result in hundreds of billions of dollars annually in lost productivity. Because of this, federal, state, and local transportation departments responsible for the nation's roads, highways, and mass transit systems are continuing to investigate

and invest in the best ways to use GPS data and systems to increase efficiencies in operations and to promote safety for those in transit.

The GPS enables automatic vehicle location systems and in-vehicle navigation systems that are widely used throughout the world today. By combining GPS position technology with systems that can display geographic information, or with systems that can automatically transmit data to display screens or computers, a new dimension in surface transportation is realized.

When used with GIS, those organizations and agencies can use GPS data and information to monitor the national infrastructure and better allocate resources to fix problems as they arise. For example, many state and local governments rely on GPS data to help monitor transit vehicle activity, including their locations, in order to keep passengers informed on precise arrival and departure times as well as scheduling delays. Mass transit systems use this capability to track rail, bus, and other services to improve on-time performance, and in the case of accidents, to direct support and emergency services to problem locations even if passengers or transit workers are unable to do so.

In addition to its applications in private vehicles and the support of the nation's infrastructure, GPS data is used by commercial ground-shipping companies to speed the delivery of cargo. By using GPS data and devices, companies can track shipping fleets worldwide, record the movement of vehicles associated with those fleets, and control route planning. Using GPS technology to track the movement of freight has improved many companies' logistical operations and their interface with consumers through services such as "time-definite delivery." This capability improves the overall efficiency of those operations, increasing the overall economic benefit to the companies and their consumers.

Additionally, many nations use GPS data to help survey their road and highway networks by identifying the location of features on, near, or adjacent to the road networks. These include service stations, maintenance and emergency services and supplies, entry and exit ramps, damage to the road system, etc. The information serves as an input to the GIS data-gathering process. This database of knowledge helps transportation agencies reduce maintenance and service costs and enhances the safety of drivers on the roads.

The U.S. government credits the GPS with ensuring higher levels of safety and mobility for all surface transportation system users, more accurate position determination to provide greater passenger information, more effective monitoring to ensure schedule adherence, creating a transit system more responsive to transportation users' needs, better location information with electronic maps to provide in-vehicle navigation systems for both commercial and private users, and increased efficiencies and reduced costs for surveying roads.

Using GPS technology to help track and forecast the movement of freight has created a logistical revolution, including an application known as time-definite delivery. In time-definite delivery, trucking companies use GPS data for tracking to guarantee delivery and pickup at the time promised, whether over short distances or across time zones. When an order comes in, a dispatcher initiates a computer function and a list of trucks appears on the screen, displaying a full array of detailed information on the status of each. If a truck is running late or strays off route, an alert is sent to the dispatcher.

Aviation

Another area in which GPS is a vital component of improved operations is aviation. Similar to how GPS data support safety and efficiency of ground travel, GPS assists with increasing the safety and efficiency of flight around the world. With its accurate, continuous, and global capabilities, GPS provides data for seamless satellite navigation services that satisfy many of the requirements of aviation users. Space-based positioning and navigation enables three-dimensional position determination for all phases of flight, including departure, en route, arrival, and airport surface navigation.

New and more efficient air routes made possible by GPS data are continuing to increase, resulting in time and financial savings. For example, research shows that aircraft flying over data-sparse areas such as oceans have been able to safely reduce separation between one another, which allows multiple aircraft to fly more favorable and efficient routes in order to save time and fuel and increase revenue.

As in ground transit applications, the aviation community is also seeing continuous improvements to the modernization and effectiveness of GPS data-based applications and capabilities to support an ever-expanding robust aviation system. Reliance on

GPS data as the foundation for today's and tomorrow's air traffic management system is a major part of many national plans. Aviation authorities are moving forward on initiatives aimed at documenting reductions in flight time, workload, and operating costs for both the aviation service companies and travelers. GPS data also serve as an essential component for many other aviation systems, such as the Enhanced Ground Proximity Warning System (EGPWS), which has been successful in reducing aircraft accidents.

The U.S. government credits GPS with the following benefits to the aviation community: continuous, reliable, and accurate positioning information for all phases of flight on a global basis, freely available to all; safe, flexible, and fuel-efficient routes for airspace service providers and airspace users; potential decommissioning and reduction of expensive ground-based navigation facilities, systems, and services; increased safety for surface movement operations made possible by situational awareness; reduced aircraft delays due to increased capacity made possible through reduced separation minimums and more efficient air traffic management, particularly during inclement weather; and increased safety-of-life capabilities such as the EGPWS.

Maritime

GPS has changed the way much of the world operates and this is also true for marine operations, especially in the areas of navigation and search and rescue. Since GPS data-based applications provide the fastest and most accurate method for mariners to navigate, measure speed, and determine location on the high seas, cargo shipping companies, the fishing industry, and recreation cruise companies have enjoyed the many benefits GPS data brings to their overall operations worldwide.

Oceangoing vessels encounter a variety of hazards as they negotiate the oceans' vast expanses, so navigating open seas in the most economical, safest way possible is highly dependent on the accurate position data provided by GPS data. Ship captains and crews rely heavily on GPS data to understand their ocean vessel's position and speed in order to navigate congested harbors and open waterways. Add the vast array of sea conditions to the mix, and maritime transportation operations become one of the most hazardous forms of transportation on the planet, with a greater risk of accidents and

increased difficulty in supporting search and rescue operations. The need for accurate positioning information becomes even more critical as the vessel departs from or arrives in port.

Additionally, mariners and oceanographers are increasingly using GPS data for underwater surveying, buoy placement, and navigational hazard location and mapping. Commercial fishing fleets use GPS data to track fish migrations and to navigate to potential fishing locations. From a policy standpoint, GPS data has played a role in ensuring compliance with maritime transport regulations and has helped the U.S. Coast Guard cut down on illegal fishing trade and transportation.

An enhancement to the basic GPS signal known as Differential GPS (DGPS) provides much higher precision and increased safety in its coverage areas for maritime operations. Many nations use DGPS for operations such as buoy positioning, sweeping, and dredging. This enhancement improves harbor navigation.

World governments and industrial organizations are also working to develop performance standards for electronic chart display and information systems that pull location and positioning information from GPS and/or DGPS. With the implementation of these standards, these systems continue to revolutionize marine navigation and will help phase out paper nautical charts that can prove to be outdated or inaccurate.

Similar to the GIS and mapping overlays supportive of GPS data receiving devices used in ground transportation, the information provided by the DGPS can also be integrated with radar information and digital nautical charts in an electronic format. This format provides a standard, common operating picture for many commercial vessels, with the opportunity for automatic updates of information. Additionally, GPS information is embedded within a transmission known as an automatic identification system (AIS). An AIS is used for vessel traffic control around busy seaways, which is vital to safe navigation procedures and increases security of ports and waterways by providing greater situational awareness of commercial vessels and their cargo.

An AIS transponder system is capable of communicating ship-to-ship and ship-to-shore by transmitting real-time information on the vessel's identification, location, and cargo. This is possible

due to the vessel's GPS position being embedded in these transmissions, where essential information about its movements and contents can be automatically uploaded to electronic charts and greatly enhance the safety and security of vessels using this system. The capability that comes from combining GPS, DGPS, AIS, and digital chart information serves to increase the efficiency of maritime transport operations along the world's waterways, resulting in reduced risk to vessels and cargo and increased cost savings to the overall industry and consumer base.

The role of GPS is also increasingly in the management of port facilities. GPS technology, coupled with GIS software, is key to the efficient management and operation of automated container placement in the world's largest port facilities. GPS technology facilitates the automation of the pickup, transfer, and placement process of cargo containers

and can track them from port entry to exit. With millions of container shipments moving through port terminals annually, GPS applications have greatly reduced the number of lost or misdirected containers as well as the associated operating costs.

National Transportation Infrastructure

GPS has not only had significant impact on the safety and transportation of goods, people, and services across the world's oceans and the nation's highways, it has also changed the way roads and highways are built, increasing the life cycle of the national infrastructure.

GPS data equipment has helped with the construction industry's productivity by providing accurate machine guidance and measurement technology that improve the accuracy and efficiency of many construction-related functions such as surveying, excavating, grading, subgrading,

A Federal Emergency Management Agency (FEMA) contractor attaches a GPS transponder onto one of a fleet of 300 FEMA disaster relief trailers at the Fort Gillem FEMA Logistics Center in Atlanta, Georgia, August 29, 2006. GPS helps managers of emergency vehicle fleets avoid delays in dispatching emergency services by giving them the ability to effectively identify the location of emergency responders and of police, fire, and rescue vehicles in relation to disaster survivors and others in need.

transportation management, facility delivery, urban planning, and job site safety monitoring.

Activities that once required items such as measuring tapes, compasses, and levels combined with weeks or months of intensive work by teams of specialists are now completed in a matter of hours by a single person with a GPS data receiving device. GPS surveying instruments can make precise measurements without a line-of-sight requirement and work under a multitude of weather conditions. This improves the overall construction process. Additionally, GPS contributes to the more effective management of construction material and equipment, which ultimately reduces costs and inefficiencies. Recent industry surveys suggest that more than 40 percent of civil engineering construction projects have adopted using GPS data receiving devices in the management of construction projects.

For example, GPS antennas are now commonplace on most roadwork equipment and have proven instrumental in improving how the nation's roads are built. Because of the accuracy of these receivers, engineers can ensure that the perimeters set for a particular construction project are more accurately carried out in the way they were designed. This improves the accuracy of the road being built and extends the performance and life of the materials used. For example, precision grading using GPS data in roadway construction projects has proven to reduce workload of construction crews and to increase the overall efficiency of the construction project.

Emergency Response and Disaster Relief

GPS has also become an integral part of modern emergency response systems—whether helping stranded motorists find assistance or guiding emergency vehicles. Knowing the precise location of landmarks, streets, buildings, emergency services resources, and disaster relief sites reduces the time it takes to get to those in need, saving lives in the process, and GPS is vital to informing emergency workers, first responders, and public safety personnel during these emergency and disaster relief operations.

GPS has played a vital role in relief efforts for global disasters such as the tsunami that struck the Indian Ocean region in 2004, Hurricanes Katrina and Rita that wreaked havoc in the Gulf of Mexico in 2005, and the Pakistan–India earthquake in 2005. Search and rescue teams used GPS, GIS, and

remote sensing technology to create maps of the disaster areas for rescue and aid operations and for assessments of damage. These capabilities are also integral to managing and containing the spread of wildfires as well as emergency response to storm damage and flooding in areas affected by such natural disasters. GPS precision information can help play a role in anticipating such events and helping ensure the safe evacuation of people in the affected disaster area, and in management of emergency response resources.

As the international positioning standard for use by emergency and other specialty vehicle fleets, GPS has given managers a quantum leap forward in efficient operation of their emergency response teams. The ability to effectively identify and view the location of emergency responders and of police, fire, and rescue vehicles in comparison with individuals affected by an emergency situation creates a new transportation network in a geographic area and avoids delays in the dispatch of emergency services.

In short, GPS modernization translates into saved lives by delivering disaster relief to areas in a more timely and accurate manner, saving lives and restoring critical infrastructure, providing position information for mapping of disaster regions, enhancing capability for flood prediction and monitoring of seismic precursors and events, and providing positional information about individuals with mobile phones and in vehicles in case of emergency.

Vulnerabilities, Privacy, and Policy Response

Like all radio-based services, GPS is subject to interference, and devices can lose reception due to both natural occurrences like solar flares and human-made causes such as intentional jamming devices. Since 2000, U.S. policy has worked to document these unintentional and intentional vulnerabilities in the U.S. transportation system due to the availability of and access to GPS data and the risks associated with the GPS system being the only means for position determination and precision timing. In addition, the government is currently fielding new GPS signals that are more resistant to interference. As such, many have contended that the GPS system cannot serve as the single source for location information or precise timing data in case of failure and loss of capability for critical applications. Policy members have recommended establishing backup systems and procedures for all GPS applications

where a loss of information or connectivity could result in potential life-threatening situations or major environmental or economic impacts.

As a result of U.S. policy, the U.S. Department of Transportation has worked to establish GPS backup systems or applicable operational procedures to ensure limited impact on the safety of people, goods, and systems in the event of loss of GPS signals or in which applications would be adversely affected. Additionally, the U.S. Department of Transportation has taken an active role in outlining priorities and measures for ensuring that the future navigation infrastructure's use of GPS will fulfill its role as a key element of the national transportation infrastructure. Furthermore, U.S. presidents since the onset of GPS have worked to consistently issue policies that would foster the investment and development of GPS technologies, initiatives, and capabilities for a multitude of peaceful purposes worldwide.

However, with the increased use of GPS and geolocation, or geotagging, technologies and software, many have expressed concern over the potential misuse of this information in respect to an individual's privacy. While current federal statutes do not clearly protect individuals from such misuse, congressional members are moving forward on introducing legislation to deal with these concerns. One such piece of legislation is the Geolocation Privacy and Surveillance Act, or GPS Act, which seeks to establish a legal framework that gives government agencies, commercial entities, and private citizens clear guidelines for when and how geolocation information can be accessed and used. The bill proposes creating a process whereby government agencies must obtain a probable cause warrant to obtain geolocation information in the same way that they currently obtain warrants for wiretaps or other types of electronic surveillance. Additionally, the act would prohibit businesses from disclosing geographic data about its customers without their consent. In March 2013, the bill was reintroduced for consideration by the 113th Congress and has been referred to the Senate and House Judiciary Committees and the House Intelligence Oversight Committee for review.

Similar to the GPS Act, the Online Communications and Geolocation Protection Act contains many of the same provisions and was also submitted to the 113th Congress for consideration.

The stability and transparency of U.S. policy, combined with a long track record of dependable GPS service, have laid a solid foundation for investment and innovation in GPS technology. As a result, the commercial use of GPS technology has flourished, transforming the way Americans live and work today.

GPS, Automobile

The Global Positioning System (GPS), a U.S.-owned utility, is a satellite-based navigational system developed by the U.S. Department of Defense in the 1960s to help U.S. Navy submarines determine their position more accurately. The technology, which triangulates time signals from space using satellites and ground stations, was used exclusively for military purposes until the early 1980s when the Ronald Reagan administration opened the doors to applications in the private sector.

Since then, GPS technology has evolved significantly in both scale and scope and is widely used in smartphones, computer tablets, watches, and vehicles. Some vehicle manufacturers now install GPS data-receiving functionality as part of their onboard computer systems as a standard practice; others offer it as an inexpensive add-on. For vehicles without built-in GPS receivers, there are a host of external device options available to consumers at fairly nominal cost. The ubiquitous nature of products utilizing GPS data and their increasingly in-depth services are changing the way many Americans drive.

Benefits of GPS

GPS satellites orbit the Earth, zero in on Earth-bound transmitting devices through a series of signals, and calculate how long the signals take to arrive. The result of that calculation provides an extremely accurate, real-time estimation of latitude and longitude. That near-pinpoint accuracy has helped dramatically alter the way motorists get around. For many, gone are the days of storing paper maps under the seat, stopping to ask a stranger for directions, or getting dangerously lost because a street sign was passed unseen.

GPS data offers a convenient means to facilitate efficient travel by providing a clear indication to drivers as to where they are and where they are going. Drivers can enter a destination address and, with the click of a button or voice confirmation, start the system calculating an optimal route. Drivers even have the option in most cases to fine-tune the process even further by requesting the most direct route or the one with the least amount of multilane highways or other type of preference. With most models, the GPS data receiver displays the relevant segments of the route in map form, list form, or both on a lighted screen and provides audible directions

at each juncture. If the driver misses a turn, the GPS receiver automatically recalculates the route based on the revised vehicle position. The state-of-the-art technology and user-friendly delivery can help make driving in unfamiliar areas less stressful and distracting.

GPS data receiving technology also helps motorists avoid traffic delays. Some applications using GPS data offer a feature that is capable of monitoring current traffic volume along roadways, giving drivers an opportunity to adjust their route to avoid potentially long delays. Some systems go so far as to indicate which lane to drive in. They notify the driver in advance of an exit or a shift in the road as to which lane or lanes are best to carry on with the designated route. For drivers unfamiliar with a specific major highway system, the visual and vocal cue is another useful convenience feature.

GPS also offers safety benefits. At night and during bad weather, for example, a GPS data-based application alerts the motorist to an upcoming turn or ramp long before the driver is likely to see it. It also works well on low-lit back roads by providing a preview of what is ahead. Many GPS data-receiving devices offer a night-vision version of the viewing screen, which changes automatically in dim-light conditions to ensure optimal visibility

A dashboard-mounted Global Positioning System (GPS) data receiver. GPS data is stored in the servicing company's database and may be passed on to market researchers, who then tie traffic patterns to demographic data from vehicle registration.

of the route and additional key information on the screen. Other common safety features of installed GPS receiver models are hands-free calling in case of emergency and special help buttons that direct the driver to the nearest police station, hospital, or service garage.

In addition, a GPS data device can increase security of the automobile itself. GPS data services that are part of a vehicle's computer system, such as OnStar, offer the ability to instantly map the current location of a vehicle without driver involvement. Its programming inherently records the vehicle's location, speed, route, and even safety features like seat belt use and signaling, making swift retrieval in the event of a theft more feasible. Those same features, however, may make some drivers uneasy. It is disconcerting for some to realize that their movements and the activities they engage in within the privacy of their personal vehicle are being tracked and recorded by the GPS data servicing company even in nonemergency and nontheft situations.

The data obtained by a vehicle's GPS receiver is recorded by the servicing company and stored in that company's database system. That information then may be passed on to market researchers interested in learning about driving habits and travel behavior among certain populations. For example, a company seeking to advertise to a certain consumer group may look to the GPS data to determine the best placement for outdoor advertising billboards based on who is traveling which roads and when. Those traffic patterns are identified by GPS tracking information and can be tied to demographic data based on each vehicle's registered ownership.

The U.S. Department of Transportation has tested the research validity of GPS data collection and found that GPS technologies accurately capture variability in travel behavior across multiple days and offer detailed route selection, spatial location, and travel itinerary information not readily available by other travel data sources.

While GPS technology makes the act of navigation less complicated, it is important that drivers remain alert and responsible. The allure of new technology with interactive touch screens and customizable voice options may be a distraction for some, especially newer drivers and those new to GPS, who tend to look at the navigation screen much more than is necessary. An unsafe habit that many drivers practice—even long-time GPS data users—is entering a

destination or modifying a route while engaged in the act of driving. Some of the newer installed GPS data devices will not allow reprogramming while the vehicle is in motion. For the ones without this safety measure, it is up to the driver to be responsible and pull over or wait until stopped at a light before attempting to modify GPS receiver settings.

Gravity Models

The gravity model is a general model used to describe the spatial interaction behavior of social and economic flows. In its various forms, the gravity model has been widely used for several decades in such disciplines as transportation, geography, urban and regional planning, sociology, demography, economics, health planning, and marketing to analyze and predict flows of people, goods, money, etc. In transportation, the gravity model was a

part of a string of models in the U.S. Department of Transportation's urban transportation planning (UTP) procedure used to forecast the flow of people and/or vehicles on every link of a transportation network in order to evaluate various transportation plans. Today, all commercial transportation planning packages include modules to compute gravity models.

While several versions of the gravity model have been given in the literature, in the most general definition of the gravity model, a flow T_{ij} between an origin i and a destination j is written as

$$T_{ij} = A_i B_j F_{ij}$$

where T_{ij} is the expectation, EN_{ij} , of the number N_{ij} of trips between origin i and destination j , that is,

$$N_{ij} = T_{ij} + \epsilon_{ij}.$$

The A_i is called an origin factor, B_j a destination factor, and for most applications are considered to be parameters to be estimated. The F_{ij} is called a separation factor, and for practical purposes, is specified to be

$$F_{ij} = F_{cij}$$

namely, a function of a separation measure c_{ij} . The separation measure c_{ij} may be vector valued, that is,

$$c_{ij} = c_{ij1}, c_{ij2}, \dots, c_{ijK}$$

where each component c_{ijk} is by itself also a measure of separation (for example, distance, transportation cost, travel time). The algebraic form of the function F_{cij} is set to be

$$F_{cij} = \exp k = 1/K \theta^k c_{ijk}$$

where $\theta^k = \theta_1, \theta_2, \dots, \theta_k$ are unknown parameters to be estimated from observed flows. This form is general enough for most applications of interest. Such gravity models are called exponential gravity models and can be readily estimated by maximum likelihood procedures.

Development

Early 20th-century gravity models were developed by analogy with the physical sciences. By mid-20th

century the intervening opportunities model was proposed to derive a model of flows from a different premise. The model assumed (1) that each traveler examines destinations sequentially starting with those closest to him/her and proceeding outward and (2) that each destination is chosen in proportion to the number of opportunities in it by someone who has not already accepted a closer destination. Later research showed that the intervening opportunities model is a special case of the form $T_{ij} = A_i B_j F_{ij}$ above.

In the 1950s and 1960s the gravitational analogy for the gravity model was challenged and a number of changes to the algebraic form of the function F_{cij} were proposed, for example,

$$F_{cij} = \exp(\beta c_{ij}) \quad \text{or} \quad F_{cij} = c_{ij} \exp(\beta c_{ij}).$$

During that time, particularly in transportation studies, the separation measure, c_{ij} , was changed from distance to travel time, and since travel time is usually more sensitive to transportation system improvements, it also facilitated examination of the impacts of such improvements. Another frequently used measure is generalized cost, which is a linear combination of travel time and travel cost.

In the 1960s the gravity model was derived using entropy maximization, and Alan Wilson in his seminal work derived the model

$$\begin{aligned} T_{ij} &= a_i O_i b_j D_j F_{ij} \\ \text{with } O_i &= \sum_j T_{ij} \quad D_j = \sum_i T_{ij} \\ \text{and } C &= \sum_{ij} c_{ij} T_{ij}. \end{aligned}$$

The entropy maximization approach assumed that (a) all microstates (lists of individual trips from all origins to all destinations) are equally probable and (b) the most probable meso-state (an origin-destination trip table) is the one given by the largest number of microstates. Wilson's model is equivalent to the generalized gravity model $T_{ij} = A_i B_j F_{ij}$ above by setting

$$A_i = a_i O_i \quad \text{and} \quad B_j = b_j D_j.$$

In the 1970s T. E. Smith proposed his efficiency principle, which allowed some of Wilson's microstates consisting of longer trips to be less probable than others. As a result, Smith found that the expected flows T_{ij} must be characterized by the gravity model. Subsequently, Smith proposed the

current theory of the gravity model based on axiomatic foundations. The axioms provide both necessary and sufficient conditions for the model to hold. The implication is that such theoretical arguments are a means of formulating a hypothesis that should be tested empirically. A very large number of empirical studies with the gravity model have shown that the gravity model has a sound theoretical basis.

Estimation of Gravity Models

When the number of trips N_{ij} are Poisson distributed, the resulting gravity model has the form

$$T_{ij} = A_i B_j \exp k = 1/K \theta k_{cijk}.$$

Maximum likelihood (ML) procedures are used for the estimation of the parameters A_i 's, B_j 's, and θk 's. Maximum likelihood estimates have desirable asymptotic properties (consistency, efficiency, and asymptotic normality) and are robust to distributional assumptions for realistic departures from the Poisson assumption (note that the multinomial distribution leads to identical estimates with the Poisson distribution). Furthermore, they are essentially unbiased even for a very small sample of flows. It can be proved that under mild conditions the estimated θk 's are unique. The estimates of A_i 's and B_j 's are not unique; however, if one A_i or B_j is chosen to be an arbitrary positive number, the remaining A_i 's and B_j 's are unique under the previous mild conditions.

Specialized statistical software exists that allows gravity model parameter estimation and flow forecasting among several thousands of origins and destinations. In addition, numerical methods exist to estimate asymptotic covariance matrices for ML estimates of gravity model parameters in order to obtain parameter confidence intervals and allow for significance tests.

Transportation Applications

The gravity model is widely used within the UTP framework and its extensions to estimate passenger and freight flows. Within this framework, it is interesting to observe that origin–destination travel times and/or costs (which depend on routes chosen and traffic congestion on the routes) usually become available only after the gravity model has been applied to forecast flows. This difficulty affects only the forecasting phase (not the estimation phase, when one uses base period data for which

travel times can be observed or computed using available information) and can be alleviated by combining the distribution and assignment stages of the process into a single stage.

The gravity model is also used in land use forecasting by extension of the UTP procedure. Since the trip generation and trip attraction phases require as inputs a number of inputs as independent variables measuring intensity of land use, forecasts of these variables need to be made using a land use model. If the land use model used is of the Lowry type, which is basically a gravity model, the gravity model is used to obtain inputs for trip generation, which, in turn, is used as input into a gravity model with the same separation factors.

Another application of the gravity model relates to the aggregation and disaggregation of origin–destination flows from/to a smaller to/from a larger traffic analysis zones (TAZ) system.

Green Fuels

Fuels traditionally used to power the transportation sector are derived from fossil fuels such as petroleum. However, fossil fuels have a finite supply, and scientists estimate their reserve will be depleted in as soon as 50 or as many as 120 years. Additionally, burning fossil fuels emits greenhouse gases into the environment, leading to pollution and climate change. According to the U.S. Environmental Protection Agency (EPA), the transportation sector emitted 1.745 million metric tons of carbon dioxide (CO₂) equivalent in the United States in 2011, or 28 percent of total greenhouse gas emission, an increase of 18 percent since 1990. This amount represents half of worldwide greenhouse gas emissions attributed to car travel. Greenhouse gas emissions in the atmosphere are reaching unsustainable levels, reaching 400 parts per million for the first time since CO₂ levels have been recorded, though scientists estimate this level has not been present in the atmosphere in millions of years.

Reducing the amount of emissions from the transportation sector is a global, urgent priority. This can be achieved through using alternative means of transportation such as walking or biking, engaging in fewer single-passenger trips through carpooling or public transportation, and increasing the fuel efficiency of traditional vehicles. Transitioning cars and other vehicles to green fuels offers one of the most popular strategies because the world population's enthusiasm for driving remains unabated. Several green, or alternative, fuels characterized by low greenhouse gas emissions are being used or developed; however, a number of barriers prevent acceptance and adoption of these innovations.

Biodiesel

Clean-burning and nontoxic, biodiesel, derived from new or used vegetable oils, animal fats, or recycled restaurant grease, comes in a number of grades: B100 (pure); B20 (a 20 percent biodiesel, 80 percent petroleum diesel blend); B5 (5 percent biodiesel, 95 percent petroleum diesel); and B2 (2 percent biodiesel, 98 percent petroleum diesel). The fuel is safe to handle, store, and transport and has been used in cars, trucks, boats, and even cruise ships. Biodiesel has lower emissions than traditional petroleum gasoline: B100 offers a 75 percent reduction while B20 reduces emissions by

15 percent. The EPA estimates particulate matter emissions decrease by 10 percent and unburned hydrocarbons by 21 percent. Biodiesel has similar performance characteristics as traditional diesel in terms of consumption, horsepower, and torque but offers a higher ignition value than diesel fuel. Some consumers worry that biodiesel will clog filters, but actually, it is a solvent. As such it can dislodge deposits from previous diesel fuel use, which can clog filters. Currently, the United States has 600 B20 fueling sites. As of 2004, 1,900 stations offered biodiesel in Germany for a total of 323,000 compared to 30 million tons of petroleum-based diesel. In addition to commercially available biodiesel, some individuals and cooperatives manufacture their own biodiesel fuel. Like that of ethanol, the production of diesel requires significant land outlays for the growth of crops. Most devastating might be the impact on tropical rain forests and their inhabitants, like orangutans, where the natural vegetation is wiped out for palm tree production.

Incorporating new crops such as algae into biodiesel production or utilizing waste oil offer an alternative to new growth for the fuel's raw material. An interesting and virtuous cycle has developed among biodiesel users and manufacturers around Victoria, British Columbia. Cruise Victoria Services, a sightseeing service that operates 19 buses, decided to fuel its fleet with B20 in 2007, gradually using B100 exclusively. As they increased demand, Cowichan Biodiesel Cooperative, which produces B100, needed to secure more vegetable oil for production. Instead of turning to new growth sources, they looked to the cruise ship industry and now utilize the waste of the ships that dock in Victoria. The system is local, closed loop, and good for the environment.

Electricity

Electric vehicles and plug-in hybrids operate through electric motors powered by rechargeable battery packs. Without a traditional engine, the electric vehicles have no greenhouse gas tailpipe emissions; however, the production of electricity does emit greenhouse gases unless the plant is powered by wind, solar, or water. Although the vehicles have lower fuel and maintenance costs, they are more expensive than traditional vehicles and have a limited range of 100 to 200 miles before recharging is needed. Mountainous terrain, the use of the car stereo or climate control, or climate can affect the range per charge. Each

Samples of different biofuels produced from algae are displayed at the BioProcess Algae facility at Green Plains Renewable Energy, Inc., in Shenandoah, Iowa, April 2011. Algae is currently being studied as a possible feedstock for biodiesel production and for the fermentation process for ethanol production. Algae is claimed to yield more fuel per unit area than other biofuel crops.

recharge can take up to eight hours if using a Level 1 charging station, four to five hours with a Level 2 station, or half an hour to charge the battery to 80 percent at a DC or quick-charge station. Currently, the United States boasts 5,800 public charging stations, and Pike Research estimates that more than 11 million recharging stations will be open worldwide by 2020. Without a well-developed recharging station infrastructure, electric vehicles have not become popular among mainstream consumers.

Ethanol

Once used by Henry Ford in the earliest Ford models offered for sale, ethanol (E85), a fuel made from sugar or corn, offers a biodegradable, renewable raw material as the basis of motor fuel. Many automobile companies have been manufacturing flex-fuel vehicles (FFVs), cars and trucks that can run on traditional gasoline or E85, for a number of years.

In the United States, over 7 million FFVs are on the road, but most of these are powered by petroleum-based fuel due to lack of consumer awareness and limited infrastructure, with E85 available at just over 2,400 stations in the country.

Sugarcane-based ethanol has been a popular fuel in Brazil, the second-largest producer of ethanol, for several decades, enjoying almost 50 percent of the gasoline market. Because ethanol contains less energy than traditional gasoline, vehicles require more E85 fuel to go the same distance as gasoline, and therefore drivers must fill the tank with more frequency. Vehicles powered by E85 can also have trouble starting on cold days. Otherwise, ethanol provides driving experiences similar to petroleum-based gasoline.

Ethanol has been criticized for using ingredients that might otherwise go into food and driving up demand and price for corn as well as for the

energy-intensive production it requires. To produce corn for ethanol requires significant acreage, which reduces wildlife habitat and biodiversity and impairs the earth's ability to absorb carbon dioxide. Furthermore, heavy amounts of pesticide are used to grow corn crops. Pesticides have been linked to groundwater pollution and wildlife deaths. However, governments and automobile manufacturers as well as other commercial researchers are investigating ways to make ethanol production safer and more efficient and are exploring the use of non-crop materials such as agricultural residue, including corn stalks, forestry residue including wood by-products, and substances such as algae, sorted municipal waste, and energy crops.

When manufactured from nonfood sources, the fuel is called "cellulosic ethanol" and has applications as fuel for passenger and fleet vehicles as well as for aviation fuel. In addition to seeking new raw material to create ethanol, researchers are aiding growers to discover ways to use fewer resources to produce the crops and helping manufacturers require less energy to convert raw materials into fuels. Ethanol costs and production, however, might be adversely affected by severe weather events, including droughts, which are more frequent with global warming.

Hydrogen

As explained by Joseph Romm, in simplest terms, a hydrogen fuel cell is a device that inputs hydrogen and oxygen and outputs water, energy, and gas. Hydrogen is pushed into a fuel cell stack where it is electrochemically converted to electricity, which powers a vehicle's motor. Because hydrogen fuel cells do not emit greenhouse gases, they represent an alluring option for green fuel. To be efficient in vehicles, however, fuel cells need to be small enough to fit under a vehicle's hood while powerful enough to provide the acceleration and performance drivers expect.

Consumers also expect engines to turn on with a turn of a key or push of a button, currently impossible with some fuel cells that operate at high temperatures and need time to ramp up. Additionally, fuel cells are expensive both because the technology is new and narrowly adopted and because of the energy intensity required to extract hydrogen from other particles, such as water or natural gas, which is a necessary step in using hydrogen in fuel cells. Furthermore, because hydrogen is a gas, it would

require a different delivery system and on-vehicle storage mechanisms. Current hydrogen tanks take up much more space than current gasoline tanks.

Despite the obstacles to hydrogen-fueled vehicles, many automobile companies, including Toyota and Volvo, are devoting research and development resources to practical and cost-effective fuel cell solutions. The Automotive Fuel Cell Cooperation, a joint venture of Ford and Daimler, conducts research with the goal to achieve commercial viability of fuel cells by 2015. Under certain conditions, the federal government provides tax incentives to consumers and companies who purchase hydrogen-fueled vehicles as well as to consumers and businesses who install hydrogen fueling equipment.

Natural Gas

The U.S. Department of Transportation (DOT) estimates that emissions from natural gas vehicles (NGV) are 6 to 11 percent less than from traditional gasoline, and depending on the type of natural gas, emissions across the life cycle can be decreased by as much as 29 percent according to the Center for Climate and Energy Solutions. Because natural gas fuel systems are sealed, the vehicles have no evaporative emissions. In the United States, most natural gas production is done domestically, so natural gas vehicles reduce the country's dependence on foreign oil. Cheaper than petroleum-based gasoline and sold in units of gasoline or diesel gallon equivalents, natural gas powers over 100,000 vehicles in the United States and approximately 11.2 million vehicles worldwide. Light, medium, and heavy-duty vehicles can be retrofitted to run on natural gas. Natural gas provides the same performance as petroleum-gas-fueled vehicles.

Natural gas fuel comes in several forms. Compressed natural gas (CNG) is stored in tanks at high pressure of 3,000 to 3,600 pounds per square inch. Liquefied natural gas (LNG) is stored in liquid form after the natural gas has been chilled to minus 259 degrees F. LNG must be kept cool or burned by engine so it is only suited for some vehicles, such as ships, trains, and long-haul trucks. Shell has invested in 100 LNG stations, and Clean Energy Fuels partnered with Chesapeake Energy Corporation and T. Boone Pickens to build 70 LNG stations to create "America's Natural Gas Highway." Renewable natural gas, or biomethane, is made from decaying organic material that is extracted from sites such as sewage

plants and landfills. Researchers are also working to convert algae into a source of biomethane. In Germany, Verbio has established 105 stations that sell natural gas fuel derived from agricultural waste.

Around the world, city and state bus fleets have purchased vehicles or converted existing vehicles to run on natural gas, including Dallas, Los Angeles, Phoenix, New York, San Francisco, Vilnius (Lithuania), Porto (Portugal), Brisbane (Australia), and the Mexican state of Jalisco. In the United States, catalyzed by the benefits of a natural gas fleet and enabled by a suite of federal and state grants, a number of school systems are moving to natural gas school bus fleets, including Los Angeles, Lower Merion (Philadelphia, Pennsylvania), Jordan (Utah), and Tulsa (Oklahoma). Commercial fleet vehicles around the world are also transitioning to natural gas vehicles, including General Electric, FedEx, Waste Management, AT&T, Hertz, and Tesco. UPS, which has just over 100 NGVs in its current fleet, has announced that it plans to increase that number to 800 by the end of 2014. Some companies, such as Procter & Gamble, Nike, and Walmart, pressure transportation companies to utilize NGVs to ship their goods.

While NGVs reduce emissions compared to traditional gas, propane provides less energy per gallon so vehicles require more frequent refueling. NGVs can be expensive, costing up to twice as much as conventional vehicles, and though fueling stations are increasing, they are not prevalent in the United States. The biggest disadvantage to NGV may be the hydrofracturing (fracking) process used to extract natural gas from shale mineral deposits. Although fracking has increased domestic energy production, critics note that the method requires significant amounts of water mixed with fracking chemicals. The disposal of the fracking waste water, exempt from the Clean Water Act due to a provision in the Energy Safety Act of 2005, may cause groundwater pollution and environmental damage. Since natural gas has myriad uses, the demand may increase the price of LNG and CNG, reducing its competitiveness as a fuel source.

Propane

According to the U.S. Department of Energy, 190,000 vehicles domestically and more than 14 million vehicles worldwide are powered by propane, which was first used in the 1940s to fuel vehicles.

Typically used in fleet vehicles such as school and shuttle buses, taxis, and light trucks, propane can be a viable alternative for fuel because of its effective performance, strong safety record, clean-burning qualities, and availability within the United States.

Propane-powered vehicles exhibit the same performance as gasoline engines but have greater engine efficiency and smoother engine running. Analysis using the GREET model for life cycle petroleum use and greenhouse gas emissions indicated that propane emissions were 10 percent less than petroleum-based oil, but when derived as a natural gas production by-product, emissions could be 98 percent less.

In liquid state, propane has a low flammability range and is nontoxic, nonpoisonous, and insoluble in water, but if leaked it becomes a gas and can ignite. While propane and petroleum-based gasoline have similar costs, propane produces less energy per gallon than gas, and vehicles require more frequent refueling. Propane, which is stored in tanks, typically above ground, can be offered at the same stations as traditional and diesel fuel and is dispensed very similarly to those fuels.

Vegetable Oil

Although the practice is illegal in the United States due to EPA guidelines, diesel cars and trucks can be converted to run on straight vegetable oil (SVO). Drivers can purchase refined vegetable oil or find a source of used vegetable oil from restaurants, though used vegetable oil must be filtered to remove food particles. Vegetable oil is more viscous, or thicker, than diesel oil so the conversion kits in part heat the oil to allow it to pass through the engine. SVO—renewable, nontoxic, and biodegradable—can be placed in compost piles if spilled. Because SVO is not a commercially available fuel, few studies have been conducted to examine the emissions of vehicles using SVO. Most available data suggest that emissions are significantly lower than when using petroleum-based diesel. Additionally, soot emissions are reportedly as much as 60 percent lower than with traditional diesel-burning engines.

Barriers to Adoption

David Banister has delineated several common barriers preventing the use of sustainable transportation methods, which researchers have also

applied to alternative or green fuel. First, financial barriers, or increased costs for manufacturers and consumers, reduce the likelihood of green fuel acceptance and use. Governments and private donors may subsidize research or infrastructure development. In the United States and the United Kingdom, national governments provide tax incentives and grants to individuals and some commercial fleets who purchase vehicles powered by green fuels. Even with incentives, consumers may have difficulty calculating the long-term benefits of green-fueled vehicles versus the short-term immediate costs of the vehicle if the vehicle demands a premium price, as electric vehicles do.

Technological barriers include machines and processes to manufacture green fuels, as well as concerns about the availability of raw material or structural barriers related to the infrastructure, including the retail availability of green fuels, which can dissuade companies from investing in green fuel vehicle research and development and consumers from purchasing what vehicles are on the market. Institutional barriers include the predominance of fossil fuels in the transportation industry, which breeds commitment to the status quo and fear of change among stakeholders.

The preceding three barriers impact the fourth, public acceptability, which requires that consumers favorably evaluate the fuels in terms of availability, impact, safety, and cost. With new technologies, regulatory or legal barriers can inhibit development, such as competing standards for plugs and receptacles in electric vehicles and charging stations or fear of legal challenges.

A fifth barrier, policy failures or unintended impacts, can diminish support of green fuels, as when media reported spikes in corn prices making the material cost prohibitive in some regions due to demand for corn to manufacture ethanol. Physical barriers represent the final impediment to green fuel adoption, such as limits to raw material. Equally applicable to all types of green and alternative fuels, these barriers must be tackled by governments, interested nonprofit organizations, and manufacturers if the world's drivers are to successfully transition from a fossil-fuel based transportation system.

Green Transportation

Green transportation is a concept that relates ecological and aesthetic concerns to transportation. Green transportation is associated with efforts to minimize carbon footprints and is often linked to a transportation infrastructure supporting a green milieu or more resilient cities. This concept also relates to energy systems as well as questions of urban planning and urban form (including architecture). Examples of green transportation modes include walking,

cycling, alternative-fueled vehicles, and mass transportation. Transportation is responsible for about 13 percent of global greenhouse gas (GHG) emissions and 26 percent of global CO₂ emissions. Cities consume 75 percent of the world's energy and emit 80 percent of the world's greenhouse gases. Therefore, redesign of transportation systems and cities is essential for achieving ecological objectives. Peak oil and climate change are seen as key drivers for greener cities and transportation modes. A transportation system can also affect air quality, noise, water quality, soil quality, biodiversity, and land utilization, such as transit infrastructure.

There are different ways to define green transportation. First, one can analyze the emergence of a discourse that helped define what "green" or "ecological" outcomes are. Second, one can examine the history and impacts of various technologies and explore whether they have a greater or lesser carbon footprint, are more energy efficient, or can adapt themselves to a renewable or sustainable system. Third, one can look at the land use impacts of different transportation technologies and associated infrastructure in terms of their ability to limit congestion, promote concentration, or affect aesthetic outcomes. In sum, to understand what constitutes green transportation, one must apply multiple criteria.

There are advantages and disadvantages to various green transportation modes, depending on the criterion one applies. Something may be called "green" but may only be ecological in relative rather than absolute terms. The ensemble of how different green transportation modes fit together with an ecological infrastructure could be said to constitute a "green transportation" system, with such an infrastructure working better in some cities than others.

What Is Green?

An early source of environmentalism was the idea of conservation, which placed an emphasis on preserving nature and with human beings having special responsibility for such preservation. Robert J. Brulle notes that "conservation had a resurgence under the label of Sustainable Development" in the mid-1980s. Sustainability, however, involves "many different definitions, none of which has achieved ascendancy." One key question is the extent to which governments and corporations embrace the concept and the consequences of their doing so.

In the context of green transportation, the debate centers on the ecological impacts of some modes of transportation or fuels supporting such transportation, with criticism directed particularly at ethanol-based cars or the use of alternative-fueled cars rather than mass transportation.

Barry Commoner explained a basic green principle concerning the relationship between two realms: "the natural ecosphere, the thin global skin of air, water, and soil and the planets and animals that live in it," and the human-made "technosphere." The technosphere "has become sufficiently large and intense to alter the natural processes that govern the ecosphere." The result of a clash between these two spheres has resulted in flooded cities, droughts, contamination of water and food, poisoning of bodies, and a diminished capability to provide for human needs.

Thinkers like Commoner, Seymour Melman, and Paul and Percival Goodman saw a way out of this contradiction, partly through alternative energy, alternatives to the internal combustion engine, and alternative ways to design cities. Through direct or indirect means, these kinds of interventions could lower carbon emissions. Technology and alternative plans can play an important role in solutions, with Peter Newman and colleagues arguing that "the ability to experiment and innovate" is "the tissue of hope and the core of resilience." The buildup of atmospheric greenhouse gases from land use changes and continued combustion of fossil fuels over the past century threatens to promote catastrophic changes if certain remedial thresholds are not met. Thus the ultimate criterion for what is "green" could be the combined policies and practices that put us on a transportation path that avoids the worst ecological outcomes. As of 2012, one internationally accepted estimate was that the planet should not increase more than 2 degrees C, with leading U.S. climatologist James Hansen arguing that even this threshold is far too high and that the latitude society has to emit more greenhouse gases is decreasing significantly by the day.

The Energy Dimension

In some cities, green interventions have been linked. For example, Bilbao, Spain, was the first city to use only renewable energy sources to power its subway system. Jon Rynn explains that with electrified vehicles on transit systems, "motors are located right

next to the wheels,” whereas in “an internal combustion system, the motor has to transmit [to] the drive shaft, that is, a rigid piece of steel that is turned by the power of the engine, and that in turn turns the wheels.” Electricity creates a more efficient system because it allows you “to take the power source off the vehicle,” in contrast to cars and trucks, which must carry the power sources in the vehicle.” Most important is the ability of electricity to act as a conduit between various kinds of green vehicles on the one hand (high-speed rail, heavy rail, light rail, electric buses) and cleaner or renewable energy sources on the other (wind, solar, hydroelectric power). Despite the potential advantages of electric power, there can be thermal losses when converting fuels to electricity. Even if electricity is generated by wind or solar power, there can be losses associated with moving that power to points of use. The U.S. Energy Information Administration found that “national, annual electricity transmission and distribution losses average about 7 percent of the electricity that is transmitted in the United States.”

The ability of an energy system to be green requires that it follow the principles of sustainable development. Herman E. Daly lists two key principles regarding renewable resources: “First that harvest rates should equal regeneration rates (sustained yield). Second, that waste emission rates should equal the natural assimilative capacities of the ecosystems into which the wastes are emitted.” The basic idea is that the best energy systems can be replenished with minimal waste and that the use of an energy source should not surpass the capacities of the ecosystem. For example, wind energy is renewable (replenishable). The wind turbine by weight is mostly composed of recyclable metal, with much of the rest coming directly or indirectly from fiberglass, sand, and plastic. Plastics can be recycled and can come from sustainably harvested biomass. The linkage of electric-powered cars and trains to such clean energy sources therefore has ecological advantages.

Automobiles and Alternative Fuels

Automobiles are the second-largest contributor to greenhouse emissions in the transport sector. Stephen Potter shows that 76 percent of CO₂ emissions from an average car come from fuel usage, 15 percent from emissions and losses in the system used to supply fuel, and 9 percent from manufacturing

the vehicle. The internal combustion engine dominates auto propulsion systems. There are different ways to advance green transportation alternatives, including increasing fuel efficiency, the use of alternative fuels, car sharing, and attempts to reduce automobile usage. Driverless cars might contribute to reducing fatalities and congestion (by coordinating spacing), providing some limited ecological benefits. In August 2012, the Barack Obama administration issued rules that would require automakers to almost double the average fuel economy of new cars and trucks by 2025. Fuel efficiencies can be lost to increased driving made possible by the fact that such efficiencies are equivalent to decreases in fuel costs. In contrast, fuel taxes would more unambiguously reduce fuel use. The Central London Congestion Charging initiative considerably reduced traffic into the inner city. A comparison of the pre-congestion charging (2000–02) and postcongestion charging periods (2003–07) shows increased business activity in the central charging zone and decreased performance in outer Inner London and Outer London.

Alternative fuels include (1) electricity, which as noted can be a vehicle power source, but Jean-Paul Rodrigue notes that “The low energy capacity of batteries makes the electric car less competitive than internal combustion engines using gasoline,” although the technology is improving. Such improvements would lower infrastructure costs or logistical barriers for light rail systems and could promote electric fleet vehicle use. (2) Biogas fuels (such as ethanol, methanol, and biodiesel) come from wood waste or fermentation of food crops. Production of such fuels may compete with other uses of land. Yet, *Jatropha* uses marginal land in contrast to sugarcane. (3) Hydrogen uses fuel cells to generate electricity to propel a motor vehicle, though much energy can be wasted by its storage, production and transfer. Hybrid electric vehicles link an internal combustion engine and a supplemental electric motor with a battery power source.

The private automobile continues to gain market share at the expense of public transit systems in North America, in much of Europe, and in most developing countries. Moreover, Maja Essebo and Guy Baeten discuss the following:

Tataism—shorthand for the generalisation of motorised transport and production in new

Asian growth centres . . . may dwarf the first car era and may truly globalise a socio-spatial form centred on the private motorised car.

Tataism is named after the “Tata Nano,” the world’s least expensive car. Despite increases in fuel efficiency or even the use of alternative fuels, Tataism considerably reduces many advantages coming from such green transportation approaches. Automobiles and trucks use far more land per person than alternative transportation modes.

Walking and Bicycles

Walking and bicycling’s share in the total number of trips is significant almost everywhere. Their many advantages include favorable environmental performance, the provision of door-to-door transport, their high spatial penetration, the absence of waiting times compared to public transport, their status as inexpensive transport modes, their importance to multimodal transport chains, and their contributions to human health. Potential disadvantages of these modes include their low speed (which is relative to the level of congestion of other modes or even the layout of transit routes), relatively high accident rates, low level of comfort (susceptibility to weather conditions), and physical effort required (depending on factors such as gradients, temperature and wind, although such efforts can have health advantages).

While walking is the most important form of transportation, its fuel comes from agriculture, which is seldom “clean” and often energy intensive. A green alternative would include locally grown crops using less energy to cultivate them. Rynn notes that before the advent of trains, “cities were basically only as big as could be walked in a reasonable amount of time.” While “trains allowed the first suburbs to form,” suburbs still needed to have “houses within walking distance of the rail station.” Increases in income levels, urban sprawl, and low-density construction have usually acted as barriers to nonmotorized transport modes. Nevertheless, there has been a renaissance in bicycle use in a number of European countries like Denmark, Sweden, Germany, and the Netherlands. In the United States, the bike mode share rose more than 500 percent in Portland, Oregon, between 1990 and 2009, and doubled in New York City during the same time span. The U.S. Rails-to-Trails Conservancy found that the total savings resulting from “shifting more

short trips to bicycling or walking” could range from 2.4 to 5 billion gallons of fuel, or “between 21 and 45 million tons of CO₂ a year.”

Public Transit

The collective forms of passenger-carrying transportation services go by various names, including “transit,” “public transport,” and “public transit.” Public transit includes paratransit (including vans, jitneys, shuttles, minibuses, and minibuses), bus transit (or “coaches” in the UK), trams and light rail transit, heavy rail and metros, and commuter and suburban railways. Studies cited by Potter show that a medium-sized car releases 78 grams of CO₂ per seat-kilometer, in contrast to 26 grams for a double-deck bus, 33 for a single-deck bus, 38 for light rail, 39 for an urban electric train, 40 for a minibus, 46 for a metro/underground, and 60 for an urban diesel

A bicycle parking facility at a train station in Uppsala, Sweden, in 2007. The bicycle mode share (percentage of commuters biking to work) is increasing in some U.S. cities such as Portland, Oregon, which saw an increase of over 500 percent from 1990 to 2009.

train. Studies cited by Lee Chapman found that a gasoline (petrol) car with two occupants emitted more than twice as much CO₂ emissions (grams per kilometer per occupant) as a conventional train and four times as much as a coach. Trains can do better, depending on their fuel source.

Despite its ecological advantages, the use of public transit significantly differs, depending on the country and region. Ralph Buehler and John Pucher found that the number of annual public trips per capita in Europe and North America (2005–10) was 237 in Switzerland, 139 in both Sweden and Germany, 116 in Great Britain, 87 in France, 69 in Denmark, 65 in Italy, and 51 in the Netherlands, but only 24 in the United States (with bike transit significant in both Denmark and the Netherlands). From 2009 to 2010, the share of American workers commuting by public transit was only about 5 percent, which was one-third as high as the German share. Within Germany itself, however, the share of all trips by public transit (2003–07) was 10 percent in both Muenster and Aachen, 21 percent in Frankfurt/Main, and 27 percent in Berlin.

Other Modes: Road Freight, Aviation

Road freight is the largest contributor to greenhouse gas emissions in the transport sector. Studies by the World Business Council for Sustainability have shown that freight movement uses about 43 percent of all transportation energy, and that slow-moving vehicles cause significant highway congestion. Benefits from “dematerialization” (product miniaturization, use of lighter materials, increased product durability, service sector growth) have not reversed the increase in total material consumption tied to global growth. Fuel efficiency in freight has increased and trucks can adapt to bulkier fuels like heavy fuel cells and hydrogen, but globalization has increased freight demand and transport distances. Green policies include making manufacturers more responsible for the ecological impacts of the entire life cycle of their products, the development of regional production clusters to reduce transportation costs, and use of taxation to encourage more efficient trucks or shifts to more sustainable shipping patterns. Studies have found that, generally speaking, “intermodal transport” is far more ecological than road or unimodal transport.

Aviation has produced vast quantities of global climate-changing pollutants. Chapman explains

that “aviation is now an essential part of the world economic system,” with the increased use of aircraft leading not only to landing delays that reduce fuel efficiency but also to “increased gas emissions and ultimate, an institutional failure leading to an unsustainable programme of airport expansion.” Among the reasons for such increases are “cheaper and more abundant flights.” Tourism, often tied to air travel, is a key factor tied to growth and air pollution. Green alternatives include solar-powered planes (which are now in their infancy), and substitution for aircraft by high-speed rail (HSR). HSR has cut into air modal shares in France, Japan, Spain, and the Republic of Korea.

Infrastructure, Planning, and Urban Form

Government deregulation has increased fares for mass transit, just as rising personal incomes and car ownership, decentralization of cities and regions, and periodic declines in motoring and parking have reduced mass transit usage. A kind of vicious cycle has linked spatial decentralization and use of motorized transit: more spread-out development encourages car and truck use, and vice versa. The relatively speedy and flexible door-to-door transportation system of automobiles has usually put mass transit systems at a disadvantage when trip origins and destinations are spread all over the map. In the United States, federal policies to encourage automobile and highway use, together with the existence of cheap oil, have compounded the problem of decentralization.

There are, however, barriers to this decentralized spatial pattern and associated motor usage. First, traffic congestion has slowed speed, efficiency, and fuel economy. The existing transportation infrastructure in many countries is unable to cope with further increases in the number of motor vehicles, creating congestion problems in many towns and cities around the world. Congestion reduces the time available for alternative activities, potentially making cities with severe problems less competitive.

Second, historical and physical factors can retard an urban sprawl pattern. Land scarcity may make it too costly to spread development out, with island cities and states like New York City and Singapore unable to adapt without a dense pattern. Cities like New York, built before the car era, were unable to provide many parking lots or widen their streets to accommodate the automobile.

Third, some locales have supported denser, more sustainable patterns because of the desire to preserve open space, support ecological goals, and historical preservation interests or other aesthetic values. Mark Luccarelli explains that in the United States, the diffused metropolis produced “a sprawling, visually blighted, and functionally differentiated amalgam of existing towns and cities, residential subdivisions, industrial and office ‘parks,’ shopping centers, and malls.” Growth not only comes at the expense of the surrounding countryside but also has deprived the urban core of its integrity and its amenities.

Finally, cities that offer cultural amenities, density, mass transit access, and certain aesthetic values have certain market advantages, particularly as cities compete with one another for members of a professional-managerial class, many of whom increasingly want to live in less automobile-dependent cities. Cities with amenities like bicycle paths, light rail, accessibility by walking, and the reduced need for a car will often be more competitive in attracting such professionals. Alan Ehrenhalt concludes that deindustrialization and reduced crime have produced cleaner, safer cities in the United States, leading to a process where more affluent persons stay or move into the inner cities, and the poorer can be pushed out to the suburbs. He says professionals are attracted to the city, some wanting the following:

Jane Jacobs’s 1950s version of Hudson Street in New York’s Greenwich Village, with locally owned and slightly messy bookstores, coffee-houses, and bars, and a concentration of art galleries and studios.

Some emerging trends suggest hope for urban forms that lend themselves to greener transportation modes. Ecological thinkers like Lester Brown cite “a declining interest in cars among young people,” which some link to socialization processes linked to communication technologies like smartphones and computers, a preference for urban living, or the financial squeeze facing college graduates. Parking fees have also begun to rise in many cities. A 2012 survey of 44 central business districts in the United States found only 13 percent had abundant parking availability and just six expected the construction of new parking in the next two years. Many older

persons are not able or willing to drive, so here too is an important mass transit market.

Congestion problems, the need for efficiency, and reduction of energy use/ecological impacts have led to the advocacy of greater urban density as a necessary element of any green transportation system. Greater density facilitates the use of mass transit options; walking and cycling are the greenest (most ecological) modes of transportation. Mayors in the United States, concerned about air pollution and congestion, have waged a fight to reduce automobile usage. A review by Brown found that “almost every U.S. city is either introducing new light rail lines, new subway lines, or express bus lines, or they are expanding and improving existing public transit systems in order to reduce dependence on cars.”

David Banister cites empirical research, concluding on key parameters of a sustainable city:

The key parameters of the sustainable city are that it should be over 25,000 population (preferably over 50,000), with medium densities (over 40 persons per hectare), with mixed-use developments, and with preference given to development in public transport-accessible corridors and near to highly public transport-accessible interchanges.

Density supports the needs of information sharing, and various service sectors require face-to-face exchanges or the creation of a certain milieu or localized community culture.

Policy Questions

Despite these trends, Chapman argues that aviation and motor cars are “increasingly the favored modes for passenger transport, but are also significantly the most damaging” for the environment. Such “favored modes need to be made less polluting through technological change or alternative modes need to be made more attractive via behavioral change driven by policy.” In the United States, trend data shows a strong preference for traditional cars, with fuel prices not drastically reducing car use. The small car share of the market is no longer driven heavily by real fuel prices. As cars get smaller and more efficient (even where fuel prices are higher due to taxes), it would take much higher taxes to obviate the economic advantages of better fuel economy.

The constraints on technological solutions come from the “Jevons paradox,” in which the greater efficiency of an energy system can lead to its greater use. One view is that without stiff fuel taxes in North America and China, the expansion of mass transit will not be able to reverse the tide of global warming because oil prices are currently stable-to-falling. Conversely, the taxation of fuel and vehicle miles traveled would push citizens toward denser living and reduce the number of vehicles per household. Citizens with reduced living standards and unable to afford a car could contribute to a growing mass transit lobby.

Among the policies that have encouraged green transport cities or a shift to public transport are expanding and improving public transport service; integrated and attractive transit fares; regional and intermodal coordination; pricing and restrictions on car ownership, use, and parking; and land use policies that encourage dense and mixed-use settlements. New budget priorities at the national level are of central importance; one way to get them might be through corporatist coalitions linking the government, transit manufacturers, labor unions, and social movements.

A comprehensive understanding of green transportation necessitates that one examine potential trade-offs. There are pragmatic or policy-oriented views about the short-term benefits of a given technology and infrastructure. There are also more “utopian” visions for what an ideal community looks like, such that green transportation facilitates the achievement of multiple goals (be they related to ecology, economy, energy use, mobility, or aesthetics). For example, the technology used in an electric-powered train is more or less green, but if the energy source for the train is coal or petroleum, the technology itself ends up not being very green.

Conversely, one could have a very green-powered light rail system that promotes exurban, low-density growth, and sprawl. Such a system might be green in terms of its own environmental impacts but encourage a spatial decentralization that is not more energy efficient. On the other hand, a light rail system that decreases car use might still be considered relatively green. Some suburbanization can be considered green if it breaks down the divide between “town” and “country” (urban life and rural life) and can create a green aesthetic that is valuable

on its own account, for example, “garden cities” that are small scale, pedestrian friendly, and still on the outskirts of the inner city.

Given these various trade-offs, a consideration of the utopian green transportation community that meets multiple goals is useful. So too is the study of different cities and technologies and how these fit together. Various models for green cities supporting green transportation have been compiled by the World Wildlife Fund and Timothy Beatley in *Green Urbanism*.

Greenhouse Gases

Greenhouse gases (GHGs) are chemical compounds in the Earth's atmosphere that trap heat by absorbing infrared radiation from the sun. Gases include water vapor, carbon dioxide, methane, and nitrous oxide and can be produced by natural systems as well as human activity. Carbon dioxide is of particular concern because it is the most abundant GHG and its level has been steadily increasing since the Industrial Revolution began around 150 years ago. The level of carbon dioxide increases when the amount of the gas produced exceeds the Earth's ability to absorb (or sequester) carbon through natural processes such as plant photosynthesis.

The Keeling curve, named after scientist Charles D. Keeling who pioneered the study of atmospheric

carbon dioxide, shows how the level has increased since 1958. For earlier periods, scientists have obtained information about the amount of carbon dioxide in the atmosphere by examining ice cores. The data show that before the Industrial Revolution, the level of carbon dioxide was around 280 parts per million (ppm) and increased steadily between 1850 and 1950 to around 320 ppm. Since then, the rate of increase has been much more rapid, and the level is now in excess of 400 ppm.

Relationship to Global Climate Change

Rising concentrations of GHGs cause concern because they increase the average temperature of the earth, which sets off a chain reaction that affects climate patterns in complicated and difficult-to-predict ways. Because carbon dioxide is the most important GHG, the amount of energy used by an entity has been termed its "carbon footprint."

Transportation is an important part of any discussion about GHGs and carbon footprints because it accounts for such a large share of carbon dioxide emissions (28 percent in the United States, 24 percent in Europe, and 13 percent globally), and it has been the fastest growing component over the last several years (increasing 20 percent between 1990 and 2001 for a group of 31 European countries).

The complex ways in which people affect climate has been the subject of growing and often vigorous debate for several decades. Some have been skeptical that people's actions can affect climate at the global scale and have instead attributed changes in climate patterns to natural variations rather than a more fundamental shift caused by human activity. Two specific aspects of the scientific process that have been challenging for policy makers and the general public to reconcile are the fact that all scientific studies have some statistical uncertainty associated with them and that different studies or climate models suggest various outcomes.

In contrast to those who have been skeptical about human-induced climate change, other entities have responded to the threats associated with rising GHG emission in a more proactive manner. The United Nations Framework Convention on Climate Change (UNFCCC) is an environmental treaty with the stated goal of preventing dangerous human-induced interference of the climate system. In 1997, most countries in the world signed the

UNFCCC's Kyoto Protocol, which contained binding obligations to reduce emissions of GHGs.

Although the United States and Canada have yet to ratify the Kyoto Protocol, other agreements and legislation that they have enacted do reflect growing concern about GHG emissions in general, carbon dioxide in particular, and acknowledge the pivotal role played by transportation. For example, in 2009, the U.S. Environmental Protection Agency (EPA) ruled that the current and projected levels of carbon dioxide and five other GHGs constitute a threat to public health and the welfare of current and future generations. What is noteworthy about this decision is that the EPA specifically mentioned GHG emissions from motor vehicles—mobile sources of pollution—in contrast to previous pollution regulations that had focused mainly on point sources of pollution such as factories and power plants.

In addition to national-scale initiatives, governments at a wide variety of other scales have recognized the need for legislation to address global climate. Various networks of local governments and city mayors have emerged over the past few years to share information about and promote initiatives focused on various aspects of sustainability. One prominent example of such a network is ICLEI, which originally stood for the International Council for Local Environmental Initiatives, but in 2003 the organization changed its name to become ICLEI Local Governments for Sustainability. Members of this network span the globe and comprise more than 10 megacities, 100 supercities and urban regions, and 450 small and medium-sized cities, located in more than 80 countries. While initiatives pursued by ICLEI Local Governments for Sustainability are quite broad-ranging, transportation is a pivotal factor in the move toward either low-carbon or carbon-neutral settlements.

Carbon Footprint

The concept of a carbon footprint reflects concern about GHG emissions in general and carbon dioxide levels in particular. The term *carbon footprint* is related to the concept of the ecological footprint put forward by William Rees and Mathis Wackernagel in the 1990s, which estimates the number of “earths” that would theoretically be required if everyone on the planet consumed resources at the same level as the person calculating their ecological footprint. Carbon footprints are much more specific

than ecological footprints because they measure direct emissions of gases that cause climate change in the atmosphere. The motivation behind being able to calculate carbon footprints is to quantify and reduce environmental impacts, which can be achieved either by reducing the amount of carbon dioxide produced or by increasing the amount of carbon dioxide absorbed by nature through initiatives such as planting trees. This quantification of carbon footprints has also led to increased discussion of carbon taxes and of a process known as “cap and trade” whereby entities can meet their obligations with respect to carbon footprints by making improvements in other areas.

Transportation-Related GHG Emissions

Transportation GHG emissions are the outcome of four factors: (1) vehicle fuel efficiency, (2) the carbon content of the fuel used, (3) the number of miles traveled, and (4) the operational efficiency achieved during travel. Reducing transportation-related GHG emissions could therefore be achieved by improving one or more of these parameters. While that may sound straightforward, the issue is not that simple. First of all, countries around the world are experiencing different dynamics in the underlying structure of their economies and hence different outlooks for the trajectory of GHG emissions. In developed countries, per capita GHG emissions are already high, with the United States having the largest overall and transportation-related GHG emissions in the world. In developing countries, although per capita GHG emissions are low compared to developed countries, industrial activity and population are growing more quickly, leading to faster increases in the rate of growth of GHG emissions. While each country has its own carbon trajectory, briefly examining China and the United States illustrates some of the differences facing developing and developed economies as they seek to lower their carbon footprints.

In 2006, China overtook the United States as the world's largest GHG emitter, and according to the Energy Information Authority, China's carbon dioxide emissions rose by 170 percent between 2000 and 2012. Much of China's GHG emissions come from its high reliance on coal, which supplies nearly 70 percent of China's primary energy, more than twice the world average. China has recently pledged to transition toward a low-carbon economy by 2020,

increasing its nonfossil-fuel consumption to 15 percent of primary energy consumption, and increasing the amount of forests to absorb carbon dioxide. Policies to help reach these goals include a carbon tax and national emissions trading scheme that is expected to begin in 2016. Transportation currently accounts for only 6 percent of China's total GHG emissions, but vehicle miles traveled are expected to increase rapidly with higher per capita incomes. While it is difficult to predict whether increased household income in China will translate into the same rates of growth in vehicle ownership that have occurred in other places, some researchers predict that China could have as many vehicles in total as the United States by as early as 2030. Given the implications of such a transition for global carbon dioxide emissions, many around the globe are interested in China's plans to manage its transportation-related carbon footprint.

China launched an ambitious high-speed rail service in 2007, and as of 2012 has the busiest high-speed rail network in the world with daily ridership in excess of 1.33 million passengers. By the time the system is completed (which is estimated to take place in 2020), China will have the largest, fastest, and most technologically advanced high-speed rail network in the world. In addition to these transportation innovations, China is also experimenting with building eco-cities. The country has a tremendous amount of scope to be forward-looking in how it manages its settlement patterns to accommodate its growing population. Given that most of the transportation infrastructure has yet to be built, there is also a considerable amount of scope to shape the extent to which that infrastructure will promote low-carbon energy use. For example, national policies could prioritize the adoption of alternative fuel vehicles and create a physical infrastructure to support that option by providing alternative-energy refueling stations.

Transportation in the United States contributes approximately 28 percent of the country's total GHG emissions, and emissions relating to transportation have grown faster than those of other sectors. Between 1990 and 2006, growth in U.S. transportation GHG emissions accounted for 47 percent of the increase in total GHGs in the nation. It is widely believed that implementing strategies that reduce transportation-related GHG emissions is critical to reaching national goals. As mentioned

above, reducing transportation-related GHG emissions requires exercising one or more of the following four options: (1) improving vehicle fuel efficiency, (2) decreasing the carbon content of the fuel being used, (3) reducing the number of miles traveled, and (4) improving the operational efficiency achieved during travel. Stakeholders have experienced difficulty agreeing on which path to take toward a lower carbon future.

Policies in Developed Countries

Part of the problem in reaching consensus is that some approaches require policies that change behavior (such as reducing the number of miles being driven) while others rely upon technological fixes to the problem (such as improving vehicle fuel efficiency). People's faith in the ability of technology to provide a solution to environmental problems is a fundamental reflection of their environmental values, and these vary across a wide range of dimensions including age, income, education, gender, race/ethnicity, and political affiliation. Further complicating the issue is the fact that sometimes people are prevented from undertaking behavior that reflects their environmental values because of what environmental psychologists have referred to as "social traps." One prominent example that is quite common in the United States is that people may prefer to use public transportation rather than personal vehicles but are prevented from doing so because the physical infrastructure is not available. That said, a raft of public policies inspired by smart growth, sustainable development, and sustainability goals have been enacted in the United States over the past 20 years or so.

Many land use and transportation policies adopted in developed countries across the world, but most prominently in the United States, in the past decade or so have been directed at countering urban sprawl. While difficult to define, this phenomenon is generally associated with low-density, automobile-oriented patterns of development. The extensive research on sprawl has uncovered many ills, such as the loss of agricultural land and species habitat and increased pollution from tailpipe emissions. Perhaps one of the most unpalatable outcomes of sprawl has been that Americans are having to travel more in order to access the same goods and services as they did previously, incurring what Chuck Kooshian and Steve Winkelman

have referred to as “empty miles” in the Urban Land Institute publication *Moving Cooler*. People have begun to realize that continuing to decentralize activity in this manner is creating a vicious cycle between land use and transportation that has negative implications for carbon footprints (as well as household spending on transportation). Support is growing for alternative patterns of development. Clustering housing and other activities onto the spine of transit to reduce the amount of travel that people undertake is a common theme among sustainability-oriented approaches to urban planning.

Another factor that complicates the transportation policy landscape in the United States relates to a concept known as “path dependence,” which refers to the fact that the country has already invested in an expansive transportation network consisting primarily of interstate highways. There is one car for every 1.3 people in the United States, of which only about 4 percent are alternative-energy vehicles. As a result, the technology for alternative-fuel vehicles is more advanced than the infrastructure to support it. Reducing emissions by switching to alternative-fuel vehicles is therefore limited by the extent to which financing can be obtained to build refueling stations to support a fleet that does not rely on gasoline.

Consequently, a considerable amount of faith is being placed on the extent to which the world can respond to what some people have begun to call the upcoming “carbon emergency” by improving vehicle fuel efficiency. Places experience tremendous variations in the size, age, and type of vehicles that people drive—known generally as the fleet composition—that affects the average fuel efficiency of vehicles. In Japan and many European countries people tend to drive smaller and more fuel-efficient vehicles. In contrast, until very recently, the trend across much of the United States tended to favor larger, heavier, and less fuel-efficient sport utility vehicles (SUVs) and minivans and trucks (especially in more rural areas).

Differences in fleet composition result in variations in the capacity for reductions in GHG emissions from place to place. The most scope for improvement in vehicle fuel efficiency exists in the United States, which has consistently lagged behind other countries in fuel efficiency, despite the adoption of increasingly stringent Corporate Average Fuel Economy (CAFE) standards over the years.

The International Council on Clean Transportation conducted an extensive review of major transportation policies announced since 2000 to determine the effect that they would have on global GHG levels and published its findings in a report in 2012. It concluded that spreading the world’s most advanced regulatory standards and cost-effective technologies to other major markets while supporting shifts to low-carbon modes could stabilize global transportation emissions by 2020. However, it added that despite the large magnitude of emission reductions that can be achieved from the adoption and implementation of transportation policies, these policies will not put the transportation sector on a path to reduce emissions (from 2000 levels) by 50 to 85 percent by 2050, which is the extent of economy-wide emission reductions agreed upon by governments worldwide in order to limit the increase in global temperatures to 2 degrees Celsius. Instead, it warned that achieving such reductions in the transportation sector would need to rely on a wider range of policies enacted in parallel with technological innovations in transportation.

Of particular note is their view that gains made by improving vehicle fuel efficiency will be offset by the expansion of vehicle fleets and activity in developing countries. This view underscores the limitations of relying on one particular strategy to achieve GHG emission reductions and supports the idea of a multipronged approach that includes all of the possible options available to reduce transportation-related carbon footprints.

To summarize, many stakeholders around the world recognize the need to transition to a low-carbon economy and acknowledge that transportation policies are an integral part of this decision process. That said, transportation policies cannot be enacted in isolation from other decisions that affect human settlement patterns, such as where to locate housing, jobs, and the wide array of other activities that people need to access. It is becoming increasingly evident that if global climate change is to be limited to the 2 degrees Celsius stipulated in the Copenhagen Agreement, transportation policy will need to be conceptualized with a much broader geographic scope in mind than the immediate population that any individual system may serve.

Greenways

Efforts to mitigate the impact of urbanization on people and the environment have given rise to the growth of the greenway movement. A greenway is generally a strip of open land of varying widths, including land along natural features, land reclaimed from an industrial or other use, or otherwise vacant land. Greenways usually connect communities, neighborhoods, parks, recreation areas, or other greenways. Nonmotorized transportation is encouraged in these spaces, although motorized transportation is often accommodated. Greenways provide for movement of people, animals, water, and even seeds and can be found in urban, suburban, and rural environments. Greenways found outside urban areas may stretch for many miles and may be very wide.

The development of greenways is a reaction to the rapid urbanization of the world. As cities

become larger and as the populations of cities live closer and closer to other residents, there is a desire for green space. The environmental movement led to a call for less dependence on carbon-emitting transportation. Walking and cycling have been promoted as ways to reduce pollution while benefiting the health of those who take part in these activities.

These linear strips of land provide environmentally friendly transportation corridors. Often attempts are made to form a network of greenways, thereby multiplying their usefulness by giving access to other areas. A greenway may incorporate some of the built environment of the city.

Greenways are also seen as ways to protect the environment through the nature of their settings, as with a greenway running along the floodplain adjacent to a river. Greenways can provide much-needed habitat for animals, especially in cities. In bustling cities, greenways can provide a relief from the stress of urban life. In less urban environments greenways can provide a safe alternative to travel along busy highways or country roads. As federal funds are made available for environmentally friendly transportation uses and as civic leaders are influenced by their constituents, more and more governmental entities are developing greenway projects.

Development of the Greenway Movement

Greenways are the natural development of an urbanizing society. Early precursors to greenways were wide streets, often tree-lined, with a median between the directional lanes. Parkways were the corridors that were bordered by parks or park-like surroundings. European cities were built on a grand scale and their tree-lined boulevards are ancestors of the modern greenway. Frederick Law Olmstead developed plans for the parkways that came to dot America's landscape. These were designed as sorts of linear parks and were for the pleasure of the traveler.

The early parkways were developed for horse-drawn vehicles. The Blue Ridge Parkway is a further development of the concept and provides hundreds of miles of scenic mileage. Some cities developed greenbelts as a way to buffer the city from the countryside. Unlike linear, narrow greenways, greenbelts could be very deep buffers to prevent the invasion of rural territory by the city. The

River Walk in San Antonio is a pedestrian parkway that, in many ways, foresaw the development of greenways along rivers.

Next came the development of recreational trails and parks bordering rivers, railroads, and other aspects of the city and country. In the 1970s the need to experience nature was becoming an important aspect of life. Local governments developed trails within their boundaries to give residents a way to escape, if but for a while, from the demands of the city. The use of the term *greenway* was developed during this time and may have been used first in Denver.

The city of Denver built a greenway along a river running through the municipality. This was the era of the effort to build bike paths in cities. The early environmental movement played a part in this era of the greenway movement, fostering greater efforts to experience nature. It was during this time that the Rails-to-Trails movement began. A changing economy and the advance of the highway system led to the abandonment of hundreds of shorter railway lines that were no longer economically feasible. Many of these abandoned rights of way held by railways have been turned into greenways. If the rails are still in place, they are removed and replaced by pathways with a variety of surfaces. Some are very short and some run for many miles, such as the KATY trail in Missouri. They provide recreational pathways with various uses.

The most recent stage of greenway development has seen a multiplication of purposes for new projects, including conservation of soil and wildlife, flood protection, recreation, and the beautification of town and country. Advances in the ecological sciences and civil engineering, along with other studies, have led to a more advanced level of greenway planning. Whereas earlier stages of the greenway movement had to do with aesthetics and recreation, more recent greenways add great environmental benefits to enjoyable and beautiful scenery. Some greenways help preserve and highlight important historical sites.

Purposes

One of the major purposes of an urban greenway is to provide a context for recreational activities. In a stressful urban world, people can be renewed by activities especially available in an environment where plants and animals exist in abundance and

where there are open spaces. Biking, walking, running, skateboarding, and rollerblading are only a few of the ways in which people are able to exercise and relax in a place like an urban greenway. One study found that 75 percent of trailway use is for recreational purposes. While the purposes of greenways have grown more diverse, at the heart of many greenways is the recreational benefit.

Even when the primary purpose may be environmental or cultural, the recreational benefit is still there. Sometimes the activities provided for may be what draws public support for the project. It is fairly easy to put in recreational trails in most greenways. Multiuse trails draw the largest numbers to a greenway. Sometimes crowding becomes an issue.

A more recent trend has been to develop greenways for the environmental benefit they provide. It might be that a stream or river often floods, and land that might have been used for crops or even for buildings can be repurposed as a floodplain. Most of the time, the land will not be flooded and will be available as open space and even for recreational use. Conservation of soil has gained more importance in recent years. Erosion causes the loss of valuable land and also the silting of rivers and streams downstream. The areas immediately adjacent to streams and rivers, when floodplains are not provided, are often poor habitats for native species due to the engineering that must be done along the bank.

Included in a greenway, less aggressive steps can sometimes be taken, allowing for a less disturbed habitat. Greenways provide habitats for plants and wildlife. Greenway corridors often provide means of access between larger tracts of habitat for wild animals. Animals are able to roam more freely and safely when these greenways connect larger habitats. Plant seed production takes place in greenways, thereby ensuring some additional natural source for plant reproduction. Greenways can provide a good buffer to noise and light pollution in urban areas and along roadways.

Due to the diversity of ecology in greenways and the attraction they provide for the public, they are now often used as outdoor classrooms and learning centers. Various educational entities use these outdoor habitats to encourage conservation and to equip individuals to be advocates for the environment and for the species that inhabit greenways. More recently, the greenway movement has

South Minneapolis's Midtown Greenway provides bicycle and walking pathways along 5.5 miles of a former railroad corridor. Organizers claim that biking through the unobstructed greenway can be a faster way to make short trips through the city compared to driving. However, one study has found that trailway use in general tends to be as much as 75 percent recreational.

expanded to include efforts to stimulate the economy of areas surrounding greenways. Since these spaces can provide a large draw of people to the area, they can be a boon to businesses that cater to the wants and needs of these visitors. Restaurants provide one example of such a business. People get hungry and thirsty as they exercise along a greenway. Restaurants and other outlets for refreshments at either end of the route, or adjacent to the route, can earn substantial revenue. Property values can even increase by being located on or near a greenway. This can activate investment and building near greenways. Of course, the increased investment in building can also have negative impacts on the environment. It would be ironic to see greenways lead to further environmental degradation.

Policies and Planning

Barriers to greenway establishment have to be taken into consideration in the planning process. Financing of greenways is a major issue. In an age when governments at all levels are cutting back on nonessential expenditures, the competition

for dollars can be a huge obstacle. Acquiring the land for a greenway can be time-consuming and very expensive. If a greenway project is to succeed, there must generally be strong support from the community. The cost-to-benefit ratio may be used by the public in deciding whether to support the greenway. If the public sees great benefit in the greenway, it may be more likely to support the expenditure of public funds for the project. Landowners adjacent to the greenway may present an obstacle to development.

Some fear a reduction in their property values, possibly through limitations on activities on their land near the greenway. Others fear that the greenways will cause a decrease in the security of their property due to the large numbers of people who may travel the greenway. There may also be resentment of the loss of privacy caused by the influx of people to the greenway. Some oppose any government action that places any restrictions on the use of private property. Sometimes greenway development will infringe on private property rights. Some have resorted to threats of violence

and even destruction of greenway infrastructure in their opposition.

When greenways are planned, the requirements of the Americans with Disabilities Act must be taken into consideration. Any barriers to those with disabilities, especially along pathways, should be mitigated. The complex purposes of greenways means that the planning process must be detailed and thorough. Since greenways accomplish much more than providing a scenic recreational venue, the other purposes must be carefully studied. An example, discussed below, is the Lafitte Corridor Greenway project in New Orleans. This project has been studied for years and a number of different planning documents have been prepared. One key lesson is that a multitude of factors must be considered and the planning process may move at an exceedingly slow pace.

Greenways with good pedestrian planning can aid the effort to create walkable communities. Proper zoning ordinances contribute to communities with regard given to walkers. Greenways can fill a valuable role in lessening dependence upon the automobile for local needs. Pathways in greenways should be kept as far as possible away from roadways. Special attention should be given to the intersection of greenways with roadways. These intersections may present a risk of serious injury risk for travelers using greenway paths. Isolation from roadways along most of the greenway can lead users to complacency when they do come into contact with motorized traffic. Proper signage and approaches are necessary to prevent needless accidents.

One avenue for successful greenway development is local action. In some areas, especially urban areas, neighbors have a deep desire to see any green space conserved. To prevent commercial development, neighbors may join together in an effort to establish a greenway project. Local initiatives have the best chance of success. A limited project in one neighborhood may spur adjoining neighbors to push for the project to extend to them. A greater greenway may result when several neighborhoods come together to protect the availability of a greenway for their particular neighborhood. The final result, after local and regional input, may result in a significant greenway.

In the face of economic constraints, future greenway projects will require unusual public support

if they are to succeed. Collaborative efforts are more likely to result in a completed greenway. The busy pace of life in both urban and rural communities will continue to point to the need for the slower pace of life in a greenway.

The Lafitte Corridor Greenway Example

An interesting greenway is being developed in New Orleans along a 3.1-mile right-of-way that is primarily owned by the city. A portion of the right-of-way once was the site of a shipping canal that connected a natural waterway, Bayou St. John, to the French Quarter. This canal was a means of transporting goods into the city. A railroad also occupied part of the corridor. The canal was filled in many years ago and the railway has been abandoned. Efforts to create a greenway have gained interest through the years, and after Hurricane Katrina the city made the Lafitte Greenway Corridor a priority. A comprehensive plan for the city, the Unified New Orleans Plan, noted that the corridor would have a high recovery value.

In 2007 the city council passed a resolution dedicating the city-owned portions of the proposed greenway for the project. The greenway would connect the historic French Quarter with the Lakeview neighborhood, which was hard hit by the flooding of Katrina but has experienced dramatic recovery. The proposed greenway runs through nine neighborhoods of New Orleans.

Beginning at an internationally known historical location like the French Quarter, such a greenway would draw much tourist attention as well as provide much-needed recreational space for locals. The greenway would capitalize on the cultural richness of New Orleans and its neighborhoods and also on the long history of the city, with the route following the old bed of a historic shipping channel. The route also starts near the site of Congo Square, which has much cultural significance.

The corridor's development includes the greenway itself and the neighborhoods within a quarter mile of the greenway. It is hoped that the greenway will be a catalyst for economic growth in the immediate surrounding areas. A 16-acre park is planned for the area as well as bike and walking paths. Numerous efforts have been made to gain public support for the greenway, including organized hikes along the route. These hikes have

raised awareness of the project and have probably advanced the effort.

An organization called Friends of Lafitte Corridor was created to provide support for the continuance of the project. The city council formed the Lafitte Greenway Steering Advisory Committee to aid the council with regard to planning and implementation issues. Members of the advisory committee are appointed by the mayor, city council, and Friends of Lafitte Corridor. Federal block grant disaster recovery funds provided to the state of Louisiana were made available to help fund the greenway project.

The city's Lafitte Corridor Revitalization Plan follows a number of other planning documents that were developed in an effort to see the greenway come to fruition. The plan notes that the very heart of the vision for the greenway is the trail that will be used by people who want to walk, run, and bicycle, and, in addition, by those who want to use a variety of other forms of recreational transportation, including horses. The project exemplifies many of the facets of greenway planning of the most recent era.

Handicapped Access

According to federal law, physically disabled people must have equal access to education, employment, and health care. In order to comply with federal law, buildings and transportation systems must meet federal guidelines as specified in the Americans with Disabilities Act (ADA). Failure to comply with ADA guidelines not only results in segregation and disenfranchisement of the physically handicapped, it also can also lead to injuries, lawsuits, and loss of funding for public transportation systems.

For people with physical disabilities, accessibility and safety are primary issues when they travel. Access to public areas, such as city streets, public buildings, and restrooms, still remain a challenge for physically handicapped travelers. A noticeable change in some parts of the world are the installation of elevators, automatic doors, wide doors and corridors, bus lifts, wheelchair ramps, curb cuts, and the elimination of unnecessary steps where ramps and elevators are not available, allowing people in wheelchairs and with other mobility impairments to use public sidewalks and public transit more easily and more safely.

History

The wheelchair was the first major improvement to increase mobility for the physically handicapped. Wheeled beds and chairs first appeared in ancient

Greek and Chinese art in the 6th century B.C.E., but the first official wheelchair dedicated to the transport of a disabled person (called an invalid's chair) was made for Phillip II of Spain in 1595. A variety of three-wheeled models appeared in Europe after the invalid's chair, the most popular being the Bath wheelchair designed in 1783 by John Dawson of Bath, England. In the 19th century, inventors made improvements to the Bath chair to increase comfort and self-propulsion. In 1916, the first motorized wheelchair was built in London. In 1932, engineer Harry Jennings built the first folding, tubular steel wheelchair that served as a model for the type used today. Jennings built this wheelchair for his paraplegic friend, Herbert Everest. Together they founded the company Everest & Jennings, devoted to the mass production of wheelchairs. To this day, Everest & Jennings wheelchairs are still sold in folding, reclining, and motorized models. Motorized wheelchairs allow for maximum independence, as a physically handicapped person does not need to rely on physical strength to operate them.

President Franklin Delano Roosevelt, who became paralyzed from the waist down due to paralytic poliomyelitis, depended on braces, crutches, and a wheelchair for transport. During his time, the discussion of physical disability was taboo, and he refused to be seen in public or photographed with his braces or in his wheelchair. Roosevelt needed assistance to get in and out of the presidential

limousine, and his limo was driven onto a ramp to avoid steps. Roosevelt's staff also provided a ramp with railings for him when he traveled by train.

Though physically disabled people with means had nurses and servants to accompany them during travel and to provide accommodations, those of limited mobility in less fortunate circumstances often remained housebound or institutionalized, depending on the level of care they required. In the mid-19th century, however, physically disabled, visually impaired, and hearing impaired individuals began attending special schools to learn how to live functional, independent lives. Living skills included how to navigate through traffic and how to take public transportation if possible.

Unfortunately, the physically handicapped often still had to have people lift them out of wheelchairs or otherwise physically carry them onto buses and trains, something that was not only dangerous but also embarrassing. Vehicle operators would not allow guide dogs to ride, causing further stress to visually impaired people. Last but not least, hearing impaired people could miss their stop if no one provided a visual cue as to when to get off the bus, train, or subway. The first underground trains were often inaccessible for wheelchair-bound individuals, as few elevators existed to bring them underground, and trains were not designed with adequate spaces for wheelchairs. For these reasons, the physically handicapped remained separated from the rest of the population.

The Disability Rights Movement

Just as African Americans fought for their civil rights in the 1960s, people with disabilities also came together to make other Americans aware of how institutions segregated them from all areas of society. The disability rights movement adopted many of the strategies of the civil rights movement, including seeking justice in Congress. The historic shift in disability public policy began in 1973, with the passage of Section 504 of the Rehabilitation Act. Section 504 stated that recipients of federal funds could not discriminate against, or deny services to, anyone on the basis of disability. The Department of Health, Education, and Welfare was tasked with developing regulations to implement Section 504, providing guidelines to all other federal agencies. These regulations mandated affirmative conduct to remove architectural

and communication barriers for the disabled, and to provide accommodations. Public transit systems, however, were slow to make changes.

In 1978, disability rights activists in Denver, Colorado, organized a sit-in and blockade of the Denver Regional Transit Authority buses. The city's transit system at that time was completely inaccessible for the physically impaired. After several civil disobedience demonstrations in Denver protesting the city transit system, the Denver Transit Authority purchased buses with wheelchair lifts. Based on the success of this campaign, the leader of this movement, Reverend Wade Blank—a nondisabled former nursing home recreation director known for establishing the Atlantis Community to allow disabled individuals to leave nursing homes and live independent lives—founded Americans Disabled for Accessible Public Transit (ADAPT) in 1983 to expand the campaign for bus wheelchair lifts nationwide.

ADAPT protesters became infamous for their tactic of immobilizing buses. They would stop a bus in front and back, and wheelchair users would get out of their chairs and crawl up the steps of an inaccessible bus. For seven years, ADAPT targeted city buses and interstate bus services such as Greyhound as well as the American Public Transport Association to build awareness of inaccessible transportation. The ADAPT campaign ended in 1990 when the Americans with Disabilities Act mandated that all buses in the United States install bus lifts for people using wheelchairs.

Physically disabled people also struggled to obtain equal access to air travel. Passengers still had to climb up and down narrow portable stairs when getting on and off an airplane. Not only was this impossible for a wheelchair-bound person, but it was also very difficult for someone in braces. Depending on the severity of their impairments, disabled people could also miss their flights and transfers if their handicaps reduced their ability to move efficiently from one gate or terminal to another. In 1986, the Air Carrier Access Act was added to Title 49 of the U.S. Code.

The Air Carrier Access Act was passed by Congress in response to the Supreme Court ruling in *U.S. Department of Transportation v. Paralyzed Veterans of America*. The Supreme Court held that private, commercial air carriers were not subject to Section 504 of the Rehabilitation Act because they

were not direct recipients of federal funds. This act requires that the Department of Transportation develop and maintain regulations that prohibit commercial airlines from discriminating against passengers with disabilities. Air Carrier Access Act regulations were published in March 1990. They clearly state that carriers may not refuse transportation to a passenger on the basis of disability, that carriers must provide passage to any individual who has a disability that may affect his or her appearance or involuntary behavior, and that carriers may not limit the number of individuals with disabilities on any flight. All trip information made available to other passengers must also be made available to passengers with disabilities.

The Americans with Disabilities Act

In 1990, the Americans with Disabilities Act (ADA) became law. ADA Title II addresses public transportation services, such as city buses and public rail transit. Title II states that public transportation authorities must comply with requirements for accessibility in newly purchased vehicles, make good faith efforts to purchase or lease accessible used buses, remanufacture buses in an accessible manner, and, if possible, provide paratransit, a service whereby individuals incapable of using the regular transit system due to physical or mental impairments are picked up and dropped off at their destinations.

ADA Title III addresses public accommodations, which include privately operated transportation and transportation depots. Title III restates that public accommodations must comply with basic nondiscrimination requirements that prohibit segregation and unequal treatment. It stresses that reasonable modifications to policies, procedures, practices, and buildings themselves must remove barriers to communication and mobility for people with hearing, vision, or speech disabilities.

Improvements to Transit for the Disabled

The United States has become a model for improving access to transportation for those with disabilities. These accommodations, federally mandated through ADA, have become a part of the American landscape and improve everyone's travel experience. The greatest improvements to handicapped access to transportation are ones that all Americans now take for granted when they travel.

Street intersections that have traffic lights must also have traffic signals for pedestrians. Pedestrians include wheelchair-bound people, as well as people in braces or those with other disabilities that affect their mobility. Traffic signals for pedestrians provide visual indication of when it is safe to cross the street, as well as the amount of time they have to do so. Some cities have begun to upgrade their pedestrian traffic signals to models that loudly announce whether a pedestrian should wait or cross. Intersections are often modified to include a ramp that will allow a disabled person to safely transition from the sidewalk to the street, then back onto the sidewalk on other side.

Vans now exist for wheelchair-bound travelers. They allow for at least one wheelchair-bound driver or passenger to ride. These vans come with a large sliding door, a ramp, and "tie downs" or a docking system to keep the wheelchair stable while the van is in motion. Some states provide wheelchair conversion services for those who own standard vans or minivans. A driver rehabilitation specialist—a physical or occupational therapist with education in disability driving issues—will assess a physically disabled person to determine what type of modifications they will need for the vehicle. The Association for Driver Rehabilitation Specialists (ADED) is the primary resource for drivers with disabilities, as well as family and caregivers of disabled drivers.

Not only must buses have ramps for wheelchairs but they also must have at least two seats for wheelchair access. After someone in a wheelchair enters the bus, the bus driver must fold up the designated seat to make space for the person in the wheelchair, then buckle a special seat belt to the bottom of the chair. Buses also have designated seating for elderly or otherwise disabled passengers; nonelderly and nondisabled passengers must yield these seats if asked. Certified service animals wearing service attire are allowed to accompany disabled passengers on the bus. Bus drivers will also apply the wheelchair ramps for the elderly, those carrying heavy packages, and anyone who looks too tired to climb the bus stairs. Buses are now programmed to provide announcements on a monitor that people can see, as well as voice announcements, to let people know when the bus is approaching a stop. Passengers ready to get off the bus do not have to stand or shout to inform the bus driver of their intentions;

The San Diego Trolley, in San Diego, California, is equipped with a handicapped and wheelchair elevator extended to serve waiting passengers at the city's Old Town Station, 2006. While some U.S. cities have completed upgrading all of their subway and train stops to make them handicapped accessible, a number are still in the process of ensuring consistent rail transit access for the disabled population.

instead, they can pull a string or push a button to let the driver know when and where to stop.

City bus systems that serve large disabled populations often have a Dial-a-Ride service. Interested riders must apply for this service and show proof of their disability from their doctor. Dial-a-Ride is particularly ideal in northern cities, when snow banks may limit access to bus stops for the physically disabled. Bus depots provide bus schedules at wheelchair level, and some have renovated their customer service counters so that someone in a wheelchair does not need to depend on another person to facilitate the bus fare exchange.

Subways and trains provide passengers maps that indicate which stops have handicapped-accessible elevators. Some cities have made all subway and train stops handicapped accessible, while others are still in the process of upgrading these stops. Each subway or train car has at least one space for

a wheelchair near the door, as well as designated seating for elderly or otherwise disabled passengers. Just like buses, subways and trains also have labeled seating by the door for elderly or otherwise disabled passengers; nonelderly and nondisabled passengers must yield these seats if asked. Certified service animals wearing service apparel are allowed to accompany disabled passengers on subways and trains. Subway cars often have maps and stops clearly posted in the line of sight for all passengers, provide announcements about upcoming stops or service changes on a monitor that people can see, and use voice announcements.

Air travel remains a challenge for wheelchair-bound passengers. The greatest improvement to air travel for the physically disabled has been the commitment to getting people with limited mobility to their flights on time. Terminals have special shuttle services for the elderly and disabled so they reach

their gate in a timely fashion; they also provide folding wheelchairs that will fit on the plane. People with disabilities have the right to pre-board the aircraft prior to all other passengers. The Air Carrier Access Act of 1986 allows service dogs or emotional support animals registered with the National Service Animal Registry who have written proof of certification and service-appropriate apparel on airplanes without a fee. Most terminals have done away with transportable stairs; instead planes are aligned with a portable tunnel that allows passengers to board/disembark from the airplane and walk or ride their wheelchair into the terminal. Restroom access and seating on airplanes still remain challenges for wheelchair-bound passengers, as passenger planes still have limited space for movement.

Wheelchair-bound travelers, as well as those with service animals, are required to provide notice to the airline of their conditions so that reasonable accommodations can be made, especially during cross-country and international flights. Some disabled passengers with service animals believe that some airlines deny them reservations, so this still must be resolved.

Harbor and Port Planning

Ports are links between the sea and the land (or rivers and land in some cases). Harbors, by contrast, are sheltered areas along a coastline where ships and boats can anchor for protection in bad weather or high seas or be moored for long periods of time while their owners are elsewhere. Harbors can be naturally occurring areas or human-made structures, where sea walls and breakwaters provide additional shelter for boats using the harbor.

Many factors are involved in the planning for harbors and ports. Is it an existing harbor or port that needs to be extended, or is it completely new and being built in response to economic factors such as changes in global trade routes? Is the harbor in a sheltered area with room to expand or does it require human-made breakwaters to be built? Is there room for expansion if the port is surrounded by a town or city? Are industries around the port closing down, giving scope for it to obtain additional land for expansion? How good are the road and rail links to transport seaborne goods and passengers from the port? Is the port capable of accommodating the ever-larger ships or does it need new quays, berths, cranes, and other equipment? Are there other nearby ports competing for the same business? These are just some of the questions that might be asked when planning change in a port or harbor, but they are not the only ones.

There are many different types of ports and harbors, each with a unique history and ranging from tiny ports receiving only a few ships each year to massive container terminals that receive the largest container ships and from ports where small numbers of people use foot ferries to the largest passenger ports where several million passenger journeys are made annually. As a result, harbor and port planning needs to take into account a range of factors, such as national or regional regulations, as well as environmental issues and the concerns of local stakeholders, including local councils, road traffic planners, tourist agencies, local residents, and nongovernmental organizations where there are environmentally sensitive areas.

Irrespective of whether it is a historical port, small or large, or a new port is being planned, the main emphasis should be on ensuring that port

users benefit from high-quality services, that those services are carried out efficiently and effectively, and that there is little or no delay for ships arriving, discharging or loading cargo and passengers, and departing from the port area.

Port Planning for Existing Ports

Historical ports can be viewed as being at a disadvantage in terms of planning for expansion. They may be limited in how much they can expand physically or how much new infrastructure can be brought on site. As an example, the largest cranes may not fit within the existing port area, meaning that the largest container ships could not be unloaded, even if the water channel and access were dredged to make it deep enough for those ships to access the port. In a river port, where the banks of the river are built up with a mix of industrial activities and housing, for example, or where there are quays and jetties along its banks, it may not be possible to widen the channel and so the geography of the port is a physical barrier to expansion.

Another factor to consider is who owns the land on which the port is built. Is it a private port, where all the land, infrastructure, and services are owned and operated by a private company or is it (less commonly) a public port, where the national or municipal government owns the land and infrastructure and carries out all the operations (or is it some combination of the two)? Who administers and operates the harbor or port will have a major impact on what it can do to change, including where the funds required will come from. Potentially, publicly owned ports will find it easier to gain permission for planned developments, but they may find it harder to get funding than does a private port, where the aim is to make a profit for the shareholders and a case for development can be justified as being needed to keep the port operating in a profitable manner. However, obtaining permission to develop the port area may be more difficult for the private port owner.

Historical ports and harbors do, however, have an advantage from the relationships developed over time with municipal or local government agencies, national government, local communities and businesses, and also, very importantly, with shipping companies that have used the port for many years. Though a port may not be able to accommodate the largest ships, it can still provide services for

the range of ships that do not require more space. In port planning it is therefore important to consider the existing port users and how to provide the services they need to make their businesses more efficient. This can include improving maintenance or repair facilities for ships in port, for example, if any minor deficiencies are identified during a ship inspection. It can also include better warehousing for goods (including bonded warehouses for alcohol, cigarettes, etc., and secure areas to store consumer electronics, for example), packing facilities where cargo can be broken down for delivery to various destinations, and access to facilities in the port for ships' crews (banking, Internet connections, shops for clothes and toiletries, for example). It can also include measures to improve local road or rail links so that cargo can enter and exit the port more quickly or provide dedicated areas for the use of a single company.

Another way to improve services, particularly in ports where working hours are limited by local restrictions, is the renegotiation of hours with local authorities as a way of retaining current port users. However, anything that may impact the local community (such as extending hours of operation) should involve discussions with the local residents or businesses to ensure they are supportive of the proposed change. Particularly if the port faces a loss of business and therefore impacts the income entering the local economy, it is also important to have public involvement in port planning because the community will also suffer from lost business.

Diversification of business activities taking place in the port and in the types of shipping or cargo companies using it may also need to be considered to bring in new business, particularly if current port users move toward containerization and move their operations to a container port, for example. In that situation ports may need to consider downsizing the area they cover by selling off land or buildings for housing or change the use of part of the port area for other activities.

Another area that historical ports can consider in port planning is working in cooperation with other ports nearby or within the region or building new terminals near its existing location. In the former case, particularly in regions such as northern Europe where there are many ports in close proximity, a cooperative approach whereby those ports combine their operations may be considered.

If there is room for expansion farther along a coast, the port may build new infrastructure and provide links by road, rail, or water between the new development and the old port area. New cargo-handling equipment and other facilities for ships could be provided in the new terminal area, while the existing area could be developed to contain administrative activities, maintenance or ship repair services, long-term storage facilities, or any activities that do not have to be at the ship–shore interface.

Planning and Building New Ports

Many new ports have been built in response to changing global trade routes for shipping, for example, with the opening up of markets for goods manufactured in China and southeast Asia and traded to Europe and North America. The result has been the development of a number of new very large ports capable of handling the biggest container ships in the Far East. It has also resulted in new ports in other areas, such as the port of Jebel Ali, Dubai, United Arab Emirates, which was built around a small port town and covers an area of approximately 52 square miles (134 square kilometers). At the time of building, Jebel Ali was the world's largest harbor and one of the largest container ports in the world.

In the building of new harbors and ports, local conditions play a part in port planning, including weather conditions, prevailing winds, and tides. If a port has not been built in the area before, what are the reasons? Is the area unsafe? What would need to be done to make it safe for ships using the harbor or port? Consideration must be given to accessibility—is the waterway or coastal area deep enough and wide enough to accommodate the types of ships that will want or need to use it. If it is not, can dredging make the area accessible and, if it can, how frequently will the channel need to be dredged to maintain access?

Another question to consider is whether there are any environmentally sensitive sites or endangered species in the area where the harbor or port is planned. If the answer to that question is yes, port planners may need to consider whether any changes to the plans can be made and how those species or areas can be protected. They may need to work with environmental nongovernmental organizations (NGOs) or other groups in planning the port area and may also need to justify the need for it to the wider community.

Ports offer employment opportunities, not only during construction but also later for dock work, office work, transport firms, and other businesses. As a result, planning for new ports (or new terminals) needs to consider whether a suitable workforce is available locally or whether it will be necessary to bring people in from elsewhere. It also needs to consider whether adequate housing for employees and their families, hospitals, schools, shops, and services already exist nearby or whether these will have to be built nearby. Transportation links by road and rail also need to be provided, not just for cargo use but also for the people working or living around the port.

Other factors that need to be considered in port planning relate to the efficiency and competitiveness of the port. If a new port is to operate in direct competition with others in the same area, country, or region, how can it stand out from that competition and attract new business? In this situation, size may play a part if it is the only port that is accessible to the largest ships. In addition, factors such as the services provided to port users, the speed of throughput of cargo from ships to shore, whether there are adequate connections and intermodal transport links from port to the hinterland, or whether new links need to be built and, if so, where they can be built also need to be considered. It is also important that the port (old or new) works in cooperation with local government agencies and national government while planning changes and developments, as their agreement is vital if change is to be achieved. Ideally, ports will work with local communities and other stakeholders in port planning to ensure they accept any changes, as their opposition has the potential to damage the port's image.

Conclusion

The main considerations in port planning are ensuring that the harbor or port is profitable and attractive to port users, that it provides all the services necessary in an efficient way and with the appropriate equipment needed to do so, and that the port is accessible from the sea and has adequate links by road or rail to the hinterland. In the planning of a new harbor or port, it is important to identify the target users and involve them in the planning process to ensure that their specific requirements are met during the development of the port area. For

historical ports, identifying target users and working to meet their needs is important, both to retain business and to bring in new business. Cooperation with stakeholders such as local and national government, local businesses and communities, and other interested parties is also necessary to ensure that planned development is supported and that good relationships exist between the port and its neighboring communities.

harbors used by fishing vessels, small cargo vessels, or passenger vessels. Although the words *ports* and *harbors* are frequently used interchangeably, they are not the same: a harbor is an area of sheltered coastline (whether natural or human-made) where ships can moor and be protected from bad weather; a port has equipment for loading and unloading ships. The world's major ports and harbors are hubs in the global transport of raw materials and manufactured goods and often also serve as hubs for passenger travel and the transportation of livestock. United Nations statistics indicate that around 90 percent of all goods traded internationally were transported by sea in 2011, with the top 20 container ports handling more than 55 percent of those goods. As a result, ports and harbors may be viewed as a target for terrorist attacks, as well as destinations for smugglers. Port security is an issue of global concern, and therefore technologies are being developed to make them safer from threats from both land and sea.

Harbor Security in a Post-9/11 World

Security of ports and harbor areas became an issue of growing concern in the wake of the September 11, 2001, attacks on the United States. Previously, security in ports was often directed at land-side threats such as the theft of cargo from ships, containers, or warehouses, and at securing the long perimeter fences to prevent individuals or groups from breaking in and stowing away on ships. Security perimeter fencing is a particular problem in ports situated adjacent to urban areas, where individuals can hide and wait for the opportunity to enter the port. Security issues in harbors were theft from or of vessels tied up overnight, for example.

Following the 9/11 attacks, a number of initiatives were introduced to provide greater protection from potential terrorist attacks on ports and the ships using them. Those initiatives included the International Ship and Port Facility (ISPS) Code, a set of measures introduced in 2004 as part of the International Convention for the Safety of Life at Sea (1974). That code places legally binding requirements on both ships and ports to ensure their security, together with recommended measures that allow them to go above and beyond the legally binding requirements should port characteristics require it. Under the ISPS Code all ports are required to prepare a Port Facility Security

Harbor and Port Security

Industry statistics from World Port Source indicate that there are at least 4,700 ports in 196 countries around the world, with more than 430 ports in the United States and more than 1,500 in western Europe. This figure does not include marinas for pleasure vessels or the many numerous smaller

Assessment conducted by a recognized security organization. Once that assessment has been carried out—examining the physical security of the port, its structural integrity, personnel protection, and transportation infrastructure, for example—and potential security threats have been identified, a Port Facility Security Plan must be developed to create a secure port environment.

The Port Facility Security Officer is responsible for maintaining an up-to-date security plan that includes the following: who can access to the port and how to identify them (for example, by using differently colored badges to identify employees or nonport workers such as truck drivers, and maintaining records of who holds badges); how to ensure the physical security of the port, including fences, office buildings, warehouses, and utilities, using security patrols, additional lighting, or specialized equipment; establishing water-side measures to prevent or minimize the threat from drug or other smugglers and stowaways on ships in port, or from small boats being used to attack military vessels if they regularly visit a port, and use of underwater security systems; identifying who should be contacted in the event of security breaches and maintaining contacts with local or national law enforcement agencies, security services, the military, border control, and customs; and identifying any specific risks in the port, in particular if the port receives ships carrying hazardous materials or chemicals, crude oil, liquefied natural gas (LNG) or liquefied petroleum gas (LPG) so that additional security can be provided when those ships are in port. In relation to drug and explosive smuggling, the security plan may include the provision of canine search teams at access points to the port and at points where containers are transferred from ship to shore and from shore to road or rail transport.

A second initiative was the U.S. Container Security Initiative (CSI), introduced in 2002, which established a system of prescreening containers in foreign ports prior to their departure to U.S. ports. CSI operational ports include many of the largest container ports by volume of cargo, with ports from around the globe participating in CSI agreements. This system includes systems to identify high-risk containers based on information about their contents. Containers are screened using direct physical inspection or the use of monitoring equipment such as x-ray machines, gamma ray machines, or

radiation detection devices. Containers may also be sealed with high-security mechanical seals or with electronic seal or antitamper technology, and they may also carry Global Positioning System (GPS) data receivers so they can be tracked at all times. The system has the benefit of improving the security of ports participating in the initiative, as it offers an extra layer of security and expertise to those ports.

Smuggling

In addition to the potential terrorist threat to ports and harbors, a number of other threats, in the form of criminal activities by organized gangs, also exist. Smuggling by sea is an effective route into the lucrative markets for drugs and other substances in western Europe, North America, and Australia, for example. Large quantities of Colombian cocaine are transported into Europe. Some of that cocaine is transported by sea to west Africa and then by road to ports on the Mediterranean coast, where it is loaded onto ships sailing to southern European ports. Some of it may be routed either directly from South America or via the Caribbean into northern Europe. In the case of Asian heroin, the main smuggling routes are from the poppy fields of southeast Asia into Australia, or from via Chinese ports across the north Pacific Ocean into the United States.

Drugs have been concealed in cargo such as concrete blocks and bananas, in vehicles being transported by sea, in the tires of such vehicles, or in mechanical equipment that would need to be disassembled in order for it to be thoroughly inspected upon arrival in a port. Drug smugglers also use small ships that discharge their cargo along unmonitored coastlines or at smaller harbors where there is a limited security presence, as even a small ship can carry drugs worth many millions of dollars. Additionally, with the vast numbers of containers transported by sea each year, Hugh Griffiths and Michael Jenks suggest that criminal organizations will take advantage of what is a simple, convenient, and cost-effective mode of transport to smuggle narcotics, tobacco, counterfeit goods, weapons, and undocumented migrants by sea.

Other examples of smuggling include vast quantities of cigarettes and tobacco smuggled from China into the European Union, with European Anti-Fraud Office statistics suggesting that this trade cost EU taxpayers over 10 billion euros per annum. There is also a global market for smuggled

A U.S. Customs and Border Protection marine unit patrols the Port of Miami, Florida, in 2007. There are more than 430 ports in the United States alone. With approximately 90 percent of all goods traded internationally being transported by sea as of 2011, and at least 4,700 ports operating in 196 countries around the world, port security is a significant undertaking in many nations.

weapons, with examples of organized crime groups that smuggle weapons such as antitank rocket launchers and antiaircraft equipment from eastern European into southern European ports. There are also examples of assault rifles and submachine guns being discovered in containers on ships in Mediterranean ports that are destined for the United States, those discoveries being made when the ship has been inspected for a completely unrelated reason.

Human beings are also smuggled around the world, with examples of undocumented migrants from the Indian subcontinent and southeast Asia stowing away in containers on vessels heading to Australia and the United States. While many such stowaways may simply be seeking a better life, organized criminal gangs may also be involved in human trafficking, where individuals not only pay for passage and documents upon arrival at their destination but are then further exploited by being forced to work for the gang as laborers or domestic

servants, for example. Some stowaways may also be drug couriers who agree to carry small amounts of drugs in return for assistance in stowing away on a ship, while others may be professional couriers who make regular journeys and are very familiar with places to hide on board and how to avoid capture once a ship arrives in port.

Underwater Security

Although security in many of the largest ports has been increased in response to a possible terrorist threat, there remains the potential threat from underwater. This may involve divers or submersible vessels such as submarines or remotely operated vehicles. Underwater mounted cameras can be used as a way of monitoring for these threats, particularly around high-risk targets. Another system being developed is the use of passive acoustic monitoring systems using hydrophones (underwater microphones) to listen for underwater movement. These

systems have been used by the military as a way of avoiding detection as they do not emit sounds, unlike the more familiar acoustic sonar systems that transmit a sound and identify the distance from the object based on the reflection of that sound. Passive systems have also been used by scientists to monitor ocean noises and track whales, for example. A passive system may prove particularly beneficial in harbor areas where there is little or no ship movement during nighttime hours and could prove useful in identifying submersible vessels because the noise generated by their motors is different from the noise of surface ships and boats. It may be more difficult to identify divers, particularly in busy port areas, and it is likely that a large number of hydrophones will be needed to operate such a system.

Harbors, Design and Engineering of

From ancient times, waterfronts have been places where news of other places was exchanged—places of commerce where goods were unloaded and loaded and where mariners and passengers embarked on ships and disembarked in safe harbors. Waterfronts were cosmopolitan places where locals met foreigners and where sailors searched for entertainment. Even the smaller harbors were bustling centers of maritime commerce.

Harbors are just as important today. Oceanographer Robert Stewart of Texas A&M University writes in his online book *Our Ocean Planet: Oceanography in the 21st Century* that small ports and harbor facilities need to grow from supporting local consumption-only economies into export economies that fuel economic growth in the 21st century.

Nature is the primary designer of harbors, but as people settled on waterways in increasing numbers, waterfront commerce became an essential part of local, regional, state, and national economies and people have helped nature shape harbors, ports, and waterfront districts. Harbors and ports function interchangeably. A harbor shelters ships and berths them. A port is a place where ships can

load and unload cargo and passengers. Waterways, ports, and harbors often face the common challenges of sedimentation of waterway entrances, failing infrastructure, wave agitation inside mooring basins, degradation of water quality, and navigation challenges from water conditions and other vessels.

The U.S. Army Corps of Engineers has been the primary designer and engineer of harbors in the United States since the 19th century; in addition, many private harbor and port engineering companies plan and implement development every year, including facilities and dredging. Waterways in the United States face new challenges in the 21st century as they accommodate container ships and implement new safety measures against terrorism.

Designing and Engineering Harbors

Modern methods of harbor design usually begin with engineering drawings and a development program after evaluation of site conditions and coastal features like winds, waves, and storm protection. Part of the development plan includes a project vision, objectives, market conditions, and often marinas, boat ramps, and waterfront parks as well as marine structural inspection, design, and rehabilitation. Dredging and disposal plans and ecological restoration and habitat creation are also part of the engineering plan. When a plan is formulated and a contractor hired, the issues of shoreline stabilization, dredging, and coastal works design are addressed and federal, state, and local regulatory requirements are implemented.

Shoreline Stabilization

Federal, state, and local agencies work continuously to stabilize shorelines and harbors eroded by wind and waves and human alteration. For example, working within the Department of Commerce, the National Oceanic and Atmospheric Administration (NOAA) uses techniques built on a foundation sand fill. Combining these methods with low rock sills to keep harbors operational, they avoid harder structures like bulkheads, rip rap, or groins to create living shorelines.

Dredging and the Environmental Protection Agency

Sand and silt washing downstream gradually fill channels and harbors in a process called

sedimentation, which is a problem from small harbors to large harbor complexes like New York–New Jersey and Boston harbors. The U.S. Environmental Protection Agency (EPA) monitors dredging of harbors to remove and reduce the exposure of marine animals and humans to toxic sediments, a process called environmental dredging. Most dredging is done to maintain or deepen navigation channels; there is a growing need for wider and deeper channels in harbors because of the increasing size and use of container ships.

The EPA requires that before dredged material is approved for disposal, it must meet three requirements: (1) there must be a demonstrated need for the dredging, (2) the dredging methods and the disposal site of the dredged material must be analyzed, and (3) the material must be tested to ensure that it will not harm the environment.

Different types of dredges are used to remove sediment from harbors. A scoop-type dredge lifts a scoop at a time. A bucket dredge is a scoop-type dredge that has many buckets that travel along a boom on cables, with teeth inserted at the opening of the buckets to enable them to dig deeply into the material. The boom is maneuvered underwater so the buckets take a scoop of sediment and travel back to the barge to deposit their load. Bucket dredges can work on large rocks or sand; this type of dredging works best in distances like harbor approaches. A clamshell dredge has two sides that close to scoop large amounts of sediment. Clamshell dredges are often used in constructing harbors when boulders or other difficult materials need to be removed. They are slow but effective. A dipper dredge has only one side and is connected to a hydraulic arm. Dredging with a dipper dredge is slower than with a clamshell, but the dipper can fit into very tight spaces.

A suction dredge uses suction to draw water and sediment into a pipe, empty the material into storage compartments fitted with dewatering devices like seeps and overflows, and deposit the sediment into a designated area. A suction dredge moves material at a constant volume; some accommodate attachments that pull sediment into the suction pipe, others just use the pipe. A cutter head suction dredge has a large rotating collar fitted with cutters, or teeth, to break off and pulverize material before it is drawn into the suction pipe. The cutter head suction dredge can remove soft

rock and coral, and it is also used to clear rubble after blasting and clamshell dredging harder rock. The auger head suction dredge has a head outfitted with one or two large augers that are attached to the suction pipe at right angles. This dredge can cut a wide, shallow path. The augers rotate and pull material from the sides of the cut to the center, where it is vacuumed up by the suction pipe. The augers can also be fitted with teeth to remove material from the bottom.

The New York–New Jersey Harbor, the largest port complex on North America's East Coast, every year handles 2 million loaded containers—nearly half the North Atlantic total, including bulk cargo. The port complex generates about \$30 billion in revenues and \$620 million in state and local taxes. As with most other American harbors and ports, the economic health of the port depends on regular dredging cycles to keep berths open and navigation safe.

According to a 2013 Market Research Report from IBIS World Dredging Service, growth for the dredging industry has been lower than forecast, but the industry is expected to rebound over the next five years, largely because U.S. ports and harbors will require dredging to provide access for increasingly large container vessels.

U.S. Army Corps of Engineers

The U.S. Army Corps of Engineers (USACE) has created works “of a civil nature” in the United States, including water resources, since the 19th century. Through its Civil Works program the USACE conducts a wide array of projects that provide coastal protection, flood protection, hydropower, navigable waters, and ports. The Corps emphasizes navigation, hydroelectric power, infrastructure support, and emergency support activities.

Dating from 1824 federal laws that authorized them to improve safety on the Ohio and Mississippi rivers and at several ports, the Army Corps of Engineers today maintains more than 12,000 miles of inland waterways and operates 235 locks. The inland waterways—a system of rivers, lakes, and coastal bays improved for recreation and transportation—carry about one-sixth of the U.S. intercity freight at half the cost per ton mile of railroads or trucks. The USACE maintains 300 commercial harbors handling two million short tons of cargo a year, and more than 600 smaller harbors.

The Coastal Engineering Manual

During the past 50 years, the Army Corps of Engineers has based its coastal engineering practice on the *Shore Protection Manual* (1974, 1984). Previously the primary engineering manual was Technical Report No. 4, (1954, 1957, 1961, 1966), but these manuals do not reflect state-of-the-art technology and knowledge of coastal processes and engineering.

In the mid-1990s, the U.S. government, through the Coastal and Hydraulics Laboratory, initiated a *Coastal Engineering Manual* (CEM). The purpose of the CEM is to provide a single, comprehensive technical document that incorporates tools and procedures to plan, design, construct, and maintain coastal projects. The CEM includes basic principles of coastal engineering, methods for computing coastal planning and design parameters, and instructions on how to formulate and conduct studies in support of coastal flooding, shore protection, and navigation projects. The *Coastal Engineering Manual* is constantly updated and is the USACE's standard for the formulation, design, and projected performance of a broad variety of coastal projects.

Water Resources Development Act of 1986

The Water Resources Development Act of 1986, or the Deepwater Ports Act, authorized 270 Corps of Engineers projects, such as port development, inland navigation, flood control, stream-bank and shoreline erosion, and feasibility and reconnaissance studies for construction or study. The act covered all features of water resources development and planning, including federal interest cost sharing, environmental assessment, and mitigation requirements.

The act directed the Corps of Engineers to consult with the National Oceanic and Atmospheric Administration (NOAA) to determine how to use NOAA's capabilities to conserve fish and wildlife and to create and improve habitat for indigenous species. The act stipulated that all future projects undertaken by the Army Corps of Engineers had to include specific mitigation plans or proof that the projects would have negligible impacts on fish and wildlife.

The Reincarnation of Boston Harbor

Oceans and lakes have historically been used as dumping grounds, and removing sediments that

have accumulated over decades and even centuries can be challenging. Harbors such as Boston Harbor have an environmental legacy from industries that poured waste into them for a century. Boston, known because it had “the dirtiest harbor in America,” was sued in the early 1980s because of pollution in the harbor. Because of the EPA and other federal, state, and local agencies and private citizens, sources of pollution have been reduced. Industries have built secondary wastewater treatment facilities and no longer release sludge in the harbor.

In September 2000, the outfall pipe carrying treated wastewater through a tunnel out 9.5 miles into Massachusetts Bay went online. The Massachusetts Water Resources Authority has since invested more than \$30 million in specialized discharge and oceanographic monitoring and in studies of water and sediment quality and health of marine species. The ongoing work has been examined and reexamined by regulatory agencies and an independent panel of scientists. More than 300 technical reports and more than 1,000 scientific papers about Boston Harbor and Massachusetts have been published since the new treatment facilities were brought online.

Container Ships: The Future of Ports—Can Harbors Accommodate Them?

Container shipping, computers and the Internet, and a new geographical configuration of world trade, have dramatically changed the relationships between harbors, ports, and cities. Dating from the 1950s, container ships are cargo ships that carry their entire load in intermodal containers—truck-size containers that can be transferred from one type of transportation to another—without being unloaded.

Container ships carry two main types of dry cargo: bulk cargo and break bulk cargo. Bulk cargoes, such as grain or coal, are usually carried unpackaged in large volumes in the hull of the ship. Break bulk cargoes are generally manufactured goods and are carried in packages. Before containerization, break bulk cargos were loaded and unloaded from the ship one piece at a time, but by putting cargo into containers sized from 1,000 to 3,000 cubic feet or up to about 64,000 pounds, cargo can be moved at once, and each standardized container can be interlocked and secured to the ship. Containerization has increased the

efficiency of moving break bulk cargoes by reducing shipping time by 84 percent and costs by 35 percent. According to the *United Nations Review of Maritime Transport 2012*, world container traffic through ports in 2011 increased to 572.8 million 20-foot equivalent units (TEUs), the highest amount ever.

The trend in both national and world shipping is toward the use of container ships, which require high-capacity container ports and harbors. This means each local port must meet certain technical conditions that include deep-water channels, extensive areas of level ground for storage and intermodal transfers, and adequate rail and motorway connections to population centers. Cooperation among local ports, government agencies, private firms, and civic groups is necessary to transform local ports to accommodate the new, larger container ships and to create new urban uses such as offices, housing, or recreation in or near the ports, whether by remodeling, reconstruction, or new construction.

Global transnational shipping corporations and their partners who strive for economic efficiency must cooperate with local government business and civic agencies to develop the local economy and to improve the quality of the local public environment. They have to negotiate with each other for agreement about harbor and port improvements. Urban planning professor Hans Harms argues that harbor improvements lagged in San Francisco because the regulatory and governing structure is extremely complicated, the income-generating possibilities remain limited, and the state harbor commission has no strong leadership.

The Burton Act of 1968 transferred authority over the Port of San Francisco from the state of California to the city of San Francisco in 1969, but the city did not take decisive action. With this transfer, responsibilities were divided among various authorities with different constituencies, and as a public agency, the Port of San Francisco was responsible for the port area and the San Francisco city planning commission was responsible for the adjacent areas. Many of the project proposals included both areas and required the two agencies to agree.

The Port of San Francisco’s specific task is to promote activities like shipping and fishing, to protect public access to the water, and to preserve the environment, but its planning power is restricted and it cannot issue bonds. Under the Burton Act, the Port

of San Francisco is supposed to generate its own income from port operations and upgrade the run-down infrastructure without any support from the state or city. Port property can never be sold or used for private purposes, and San Francisco's municipal zoning and general planning policies apply to properties adjacent to the ports, so the Port of San Francisco's revenue generation from anything other than narrowly defined port uses is restricted. San Francisco does not have a facility plan or a policy development plan.

In contrast, the Port of Oakland located across San Francisco Bay formulated a strategic plan and took initiatives to expand and attract container shipping lines. A board of port commissioners governs the Port of Oakland, nominated by Oakland's mayor and appointed by the city council. The board has broad authority to oversee the Port of Oakland's maritime cargo operations and income from port properties. Oakland's authorities had a clear mandate and the power to make the port viable economically. Oakland's port has expanded and modernized and it is the dominant container port in the Bay Area. It ranks as the fourth-largest container port in the United States and handled 2.4 million TEU in 2006.

A New Configuration of World Trade

In the first decade of the 21st century, 85 percent of the world's goods, services, and capital investments are exchanged among the three economically most powerful regions in the world: western Europe, North America, and Asia. International container volumes have increased from 47 million TEU in 1996 to more than 140 million TEU in 2008.

North America is the third-largest import market for containers at 21 million TEU, behind Asia at 40 million TEU and Europe at 30 million TEU. The trans-Pacific trade routes have the highest trade volumes (22 million TEU at 10 percent average growth rate), with 17 million TEU at 12 percent growth rate for the Far East to Europe. North America imports more containers than it exports; forecasts for growth in the U.S. container trade are greater for imports than exports.

These trends have important infrastructure planning implications. Terminals, railroads, ports, harbors, and shipping companies will be required to make major investments as the industry continues

to mature. Today, as ports, harbors, and waterways prepare for the megaships of tomorrow, improvements and expansion of ports and their harbors require informed strategies and careful planning for successful implementation.

Harbors, Environmental Issues of

Harbors and ports have historically faced problems of pollution caused by waste dumped from ships, including oil, sewage, and garbage. As early as 1543, during the reign of King Henry VIII, bylaws were introduced in some United Kingdom ports to combat harbor pollution, with fines imposed on ships caught dumping oil. With growing awareness of the environmental impacts of pollution during the 20th century came the introduction of the International Convention for the Prevention of Pollution From Ships (MARPOL) in 1973, one of the earliest international environmental conventions. A convention of the International Maritime Organization (IMO), it establishes rules to prevent ships discharging wastes (oil, noxious liquids, harmful substances, sewage, and garbage) into the sea, with limits on how close to shore they can discharge substances, areas where dumping is completely banned, and also limits for some substances.

More recently, the MARPOL Convention has also set limits on the discharge of gases into the air. For ports, that convention lays down requirements that facilities be provided for ships to discharge waste while in port, and it has gone a long way toward reducing operational pollution from ships in port. However, harbors and ports also face problems with pollution from nonoperational sources and from dredging, often a necessity to ensure that ships can continue to access them.

Water Pollution

Water pollution can take many forms. It can be caused by ships deballasting (discharging ballast) before being loaded for a voyage. Ships use ballast to maintain stability during a voyage from one port to the next. They take water on board from one region and travel to another, where they discharge it before taking on cargo. However, a major concern with ballast water is that it can contain aquatic organisms, examples of which include jellyfish, zebra mussel, small crustaceans, and phytoplankton that are not native to an area and for which there are no natural predators. This has become an increasing problem with larger ships traveling greater distances more rapidly. With faster journeys, organisms are more likely to stay alive long enough to infest another region.

Ballast water can also contain toxic substances, such as heavy metals, chemicals, and oily substances that are suspended in the water being taken on board. Ballast has also, in the past, included the use of large stones taken on board in one country and thrown over the side when the ship arrives at its destination. While not necessarily as great a problem as the organisms and toxic substances in ballast water, those stones can still cause problems in ports, particularly if they are deposited in sufficient numbers to alter currents, tidal flows, or cause a physical blockage.

Another cause of pollution in ports is the deliberate discharge of waste from ships, despite international action to prevent it. In many ports, particularly in developing countries or countries where environmental protection is not high on the agenda or in very poor areas, it remains the practice for waste to be dumped into the water. This may be in a river where the waste washes down to the sea, or it may be in a port or harbor where dumping is quick and easy or there are no

facilities into which the waste can be discharged. Oily water is produced in the engine rooms of ships and small boats, and it has been common for this to be thrown into a harbor; many small fishing harbors may have a dark ring around them at the high-water mark, which is the result of floating oily waste being left behind as the water level drops. Other things dumped into the water include garbage, plastics, packaging, old fishing nets and floats, together with sewage and the remains from fish processing done at the quayside.

Industrial and urban runoff can also be a problem in ports and harbors at the mouths of rivers and estuaries. Runoff occurs when a substance such as oil and other substances in engine exhausts from cars and trucks is deposited on the ground and then washes into a river when it rains. This may be a particular issue in areas used by large numbers of trucks, such as large industrial ports or container terminals. Other pollution from cities and towns can include garbage and litter, blown or washed into rivers by wind and rain, and sewage waste (either treated or untreated). Many industrial processes cause pollution, and industries have often, historically, been situated on the banks of rivers that have been used to transport raw materials to, or processed/finished goods from, those industries. Agricultural runoff is also an issue in many areas. Here, animal wastes can be washed from pastureland into the rivers and transported downstream; fertilizers, pesticides, and other chemicals can be washed off arable land in the same way.

While some of the water pollution in ports is visible, such as rings of oil at high-water marks, or floating plastic and other debris, much of the waste is invisible. In areas where there is little water movement, a situation in many ports and harbors, waste sinks to the bottom of the harbor and accumulates over time, and action may be needed to remove that material.

Dredging

Dredging is the use of scoops, suction devices, or other methods to remove material from underwater. It takes place in many harbors and ports, particularly where large volumes of sediment are deposited through tidal or river action, reducing the depth of the water and making it more difficult for ships to gain access. It can also occur in new harbors or ports where large volumes of material have

Floating garbage like these pieces of plastic washed up on a black rock shoreline on the island of Hawai'i are among many forms of visible water pollution affecting ports and harbors. Other types of pollution may be invisible, such as toxins found in sediment.

been removed to create an area deep enough for use by very large ships but where tidal flows bring sediments back into the port area.

Sediment can simply be large amounts of silt (fine particles of soil or sand) that is suspended in the water columns of rivers and tidal estuaries, for example, and sinks to the seabed in sheltered areas such as around a sea wall, breakwater, or jetty. However, sediment can also be contaminated by mining spoil (waste material from mines) or from naturally occurring heavy metals that are washed out of the ground and into watercourses traveling to the sea.

Other sediments can contain high levels of organic material or fertilizers washed off agricultural land or from upstream urban sewage works and industrial and urban runoff. Some studies have found a range of chemicals in sediments, including polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), dioxins, and organotins. Many ports and harbors also have residues from

protective coatings painted on the hulls of ships to prevent rusting and corrosion, together with anti-fouling paints containing tributyltin (TBT), a substance used to prevent the growth of organisms such as barnacles that might slow the ship down. These substances leach into the water and are toxic in high concentrations. Although TBTs have been banned for many years, they will have entered sediment layers over an extended period of time.

Historically, contamination of sediments also has occurred in ports closely linked with urban areas, as well as those used by ships transporting metal ores, coal, and other loose cargo. When a cargo is unloaded and the ship needs to be cleaned to receive another cargo, material can be washed overboard during the cleaning process and sink to the seabed in the slow-moving water of the port. Dredging disturbs the sediment and releases particles into the water column, which can transport it over a wide area. If the sediment is contaminated in some way, it can damage ecosystems around ports and enter the food chain as it is bio-accumulated in shellfish such as oysters that feed on suspended matter in the water column.

Balancing the need for ships to be able to access a port or harbor with the potential environmental impacts of dredging can be a complex problem, particularly in ports with historical contamination. Careful assessment of the area, including tidal flows, seasonal conditions, and which materials are in the sediment, together with an analysis of the local ecosystem may be necessary.

Harbors and Ports, Administration and Operations of

A harbor is generally a sheltered area along a coastline, in a lagoon or at the mouth of an estuary, or in a semienclosed inlet where natural formations have created a narrow entrance. Such harbors are deep enough for vessels (ships and boats) to anchor or seek shelter from weather, tides, or difficult sea conditions, and in some instances vessels may be left at anchor for long periods of time or make more frequent journeys using the harbor as a base from which to sail (for example, fishing boats or small cargo boats and foot-passenger ferries).

Generally, only limited equipment is available to vessels using harbors, unlike ports, which have much heavier equipment such as cranes and gantries for loading and unloading of larger ships or container ships in the very largest ports. There are many different types of harbors and ports, often influenced by the history of the country or region where they are located and sometimes, depending

on their ownership, the type of business activity that occurs in them, how they are administered, and how they operate.

Types of Harbors and Ports

Natural harbors occur where shelter is provided by natural formations, such as a reef, a promontory of land, or some other naturally occurring barrier that protects ships or boats from wind or tide. These natural harbors may include almost landlocked areas where regular action is necessary to maintain access. If the natural protection is deemed insufficient to offer adequate protection from wind and water currents, particularly when weather conditions erode the level of natural protection over time, human-made structures such as breakwaters, jetties or sea walls can be built to provide additional protection. Human-made harbors also occur along rivers, with jetties or quays being built alongside or out from river banks to provide shelter for vessels; in some instances, the river channel may also be deepened and widened to allow access for vessels farther inland, giving access to road and rail transport links.

A port is a human-made location on a waterway—coast, river, or lake—where ships can be loaded or unloaded using equipment such as cranes or gantries, for example. Many ports are located in towns or cities that have grown in response to the transport of goods by sea over many centuries, although more recently, ports may start with identifying a suitable location and all other infrastructure and industrial and living spaces develop in response to that, creating modern port cities.

Ports require adequate road, rail, and inland waterway (river, canal) access to transport goods farther inland, and they can differ greatly in size and in the type of activities and vessels using them. The largest ports can extend for several miles along a riverfront and contain warehouses, storage facilities, processing facilities, freight transport links, cargo and passenger terminals, and a host of other facilities that create a highly important economic resource for the country in which they are located.

With the development of containerization and ever larger ships, new human-made harbors, ports, and terminals have been built in areas previously considered unsuitable. Reasons why an area may be deemed unsuitable include the lack of natural protection from wind, sea currents, or

adverse weather conditions at certain times of the year. Other reasons include limited access to existing harbor areas because of tidal conditions (ships only able to enter and exit at high tide), where a port is situated in an urban area with only limited room for expansion, or where a port is situated next to a fragile or protected environment, often factors for ports and harbors located along tidal estuaries.

New harbors, ports, and container terminals have been built in coastal areas in response to a lack of physical space available for expansion of existing ports (with ships being forced to queue to access the existing facilities) and in areas where the existing ports cannot accept the increasingly large ships being used to transport cargo and also passengers. Those factors may result in ships and cargo being transferred to other ports in a region with suitable facilities, with a consequent loss to the local (or national) economy. They are also being built by countries as free zones or bonded areas, where taxation rates are lower than in the rest of the country and customs regulations are less strict, giving an economic incentive for shipping and cargo companies to use the facilities offered by those ports and to develop new trading partnerships between countries.

Port Ownership and Administration

Port ownership traditionally falls into three categories: public sector, private sector, and a combination of both public and private. Those combined ports are further categorized as landlord ports, where the port is operated by a private company but the land and infrastructure is owned by the public body, which also regulates the port, and comprehensive ports, owned and operated by private companies but regulated by a public body or government. In comprehensive ports, regulatory functions such as traffic management, providing essential services, and setting regulations are the responsibility of a public body, but the land on which the port is built and operations that take place within the port are owned by a private company.

In addition to the general categories of port ownership described above, there are also other port types that may be specific to a country or region, or dependent on local circumstances such as national government regulation. Examples of other port types include trust ports, where independent

bodies have taken on all the port functions, set their own rules, and are run by independent board members on behalf of stakeholders; and charitable trusts, which depend on donations from the public to cover at least some of the costs of ensuring the port remains open.

Irrespective of port type, there are a number of functions that must be provided by and administered on behalf of the port. These are regulatory, landowner, and operational functions. Regulatory functions include enforcing laws and regulations, whether local, national or regional; providing vessel traffic management systems to ensure safe access and egress; licensing all activities that take place in the port; and safeguarding the interests of port users.

Landowner functions include but are not limited to maintaining and developing the land on which the port is built; maintaining infrastructure, including the water channel (to ensure the port remains accessible) and any protective measures (breakwaters, jetties); maintaining access road and rail links; building and maintaining office buildings, warehouses, and fixed equipment (including fixed cranes); and implementing policies to develop the port to meet the requirements of its users and owners.

Operator functions deal with the safe and appropriate transfer of goods (and passengers) from ship to shore, whether that is handled by the public sector agency or a private company.

In publicly owned ports, a Port Authority, generally established under national legislation, has responsibility to regulate all the activities of the port by ensuring that all appropriate laws are enforced (national or port specific, including labor laws and environmental regulations) and that there is adequate security in the port. The authority also administers all the land on which the port is located and all its assets, and also controls all port operations on behalf of the public. Port Authorities may also be responsible for ensuring that the port is adequately financed, that public safety is secured, and that adequate policing is in place. Public ports may be owned by a national Port Authority, usually part of a national government ministry (for example, a Ministry of Transport), or by a local municipality or council body.

In privately owned ports—single ports or large companies owning multiple ports within one

country or in several countries—all the functions of the port (regulation, land ownership, and operation) are owned by a private-sector company with the ultimate aim of making a profit for shareholders.

However, it should be noted that even in fully private ports, a Port Authority or other public body may still have some responsibility for ensuring that the private port operates within national or regional laws. This may include ensuring that the port adheres to legislation on working conditions for its employees, meets environmental standards set nationally or internationally, and maintains appropriate security and liaises with relevant agencies (police, border control, or security forces). In particular, ports are required to adhere to the requirements of the International Ship and Port Facility Security Code.

In addition to the administrative activities outlined above as being the responsibility of the Port Authority, there are a number of other administrative functions that are vital to ensure the safe and efficient running of a port or harbor. Those functions are generally managed by a Harbor Master (in small ports) or by administrative staff in the Harbor Master's Office in larger ports.

Those activities include handling day-to-day communication with port users, including ship's masters, shipping agents, cargo company agents, and external agencies such as waste companies, utilities (electricity, water, sewage, gas), and municipal council bodies, including traffic and road planners, building inspectors, and local police, for example.

They also have responsibility for collating statistics on numbers of ships visiting the port, types of cargos, maintaining weather and tidal data, ensuring that appropriate permits are held by companies and their workforce, and ensuring that relevant forms and guidance notes are made available to/adhered to by port users. In respect to inspections in ports, they need to provide a point of contact between inspection agencies and the ships or cargoes to be inspected, collating statistics for relevant agencies in that respect.

Port Operations

In addition to the administrative activities undertaken by the Port Authority and the Harbor Master's Office, there are a number of day-to-day

activities necessary to ensure that the port operates efficiently and effectively. Port operations can cover a range of services offered to ships using the port or to cargo operators on the land.

Services offered to ships include ensuring that they have somewhere to berth upon arrival in port, providing vessel traffic services such as radar, VHF radio communication, and other technology to track vessel movements in and around the port area, and making ship's masters aware of any restrictions for entry, including tidal conditions or local by-laws requiring ports to operate only during specific times. Other services offered to ships can include providing navigational aids such as charts, details of waypoints where the ship must change direction, and details of any wrecks or obstructions that need to be avoided.

Larger ports may also provide pilotage services where entry to the port is difficult due to local tidal conditions, hidden obstructions, or other hazards. In this case a pilot is transferred onboard ship and takes control of navigation to ensure its safe passage into the port area. Towing services, where small tugboats are used to pull (or push) larger vessels to a berth, may also be provided, and this is particularly useful when a ship entering the port is very large and unwieldy and takes a long time to come to a full stop under its own power.

Barges to remove some types of dry or liquid cargo can also be used, for example, if that cargo is being transferred to an inland waterway, so that it does not have to be landed on the quayside. Barges may also be used to remove waste oil, sewage, or garbage from a ship. Ports may also offer services for the delivery of fresh drinking water, food, or fuel and provide quayside connections to electrical power.

Services offered to cargo companies include provision of facilities to load/unload cargo (cranes, gantry cranes, fork-lifts, conveyor belts), to break cargo down into smaller loads (arriving cargo) or combine it into larger loads such as containers (departing cargo), and ensure that storage for solid or liquid cargo is available. Other services provided to cargo operators may include provision of areas within the port where cargo can be packed, sorted, and labeled; documents checked; and customs inspections carried out before the cargo is loaded on trucks or trains to be transported to its final destination.

Particularly in larger multiuse port, the more services the port can offer to shipping and cargo companies, the more likely it is that those companies will continue to do business with the port and it will remain economically viable. Ports must be responsive to the needs of user groups, while at the same time ensuring that they adhere to local and national regulations, such as those for security, border control, and customs, excise, environmental measures.

An efficient Harbor Master's Office, therefore, plays a vital role in both the administrative and operational aspects of the port, irrespective of the ownership of that port.

Hazardous Materials Transport

Although the transportation of hazardous materials (hazmat, or “dangerous goods” as they are often labeled outside the United States), may seem unnecessary, these substances include items necessary for contemporary lifestyles, including fuel, certain aerosols and adhesives, and even ethyl alcohol. Other hazmat includes biological or chemical substances used in academic and medical research. Myriad state, federal, and international agencies regulate the transportation of hazardous material to protect the safety of humans, property, and the environment because the cost of accidents is much higher when dangerous goods are involved. Though agencies and stakeholders have worked together to mitigate the dangers of hazmat transport, new controversies and debates continue to emerge both within the United States and abroad.

The U.S. Code of Federal Regulations defines hazardous materials as substances “determined by the Secretary of Transportation to be capable of posing an unreasonable risk to health, safety, and property when transported in commerce, and which has been so designated.” Explosives, ordnance, poison, flammable gases and solids, corroding agents, radioactive materials, oxidizers, ammunition, fireworks, combustible gases, as well as other regulated material such as those that could potentially damage the transport vehicle or other noxious, toxic, and irritating substances are included in the category because of their potential risk to health, safety, and property. These substances are categorized into nine classes: explosives, gases, flammable liquids, flammable solids, oxidizing substances/organic peroxides, poisonous (toxic) and infectious substances, radioactive material, corrosives, and miscellaneous dangerous goods.

Yearly, over 3 billion tons of hazmat, or 28 percent of the annual freight ton-miles, are transported in the United States by land, rail, sea, air, and 2.6 million miles of pipeline. Though estimates of the amount of hazmat transported outside the United States are not available, the total volume of hazmat movement internationally likely reflects a significantly larger amount. For example, the United Nations Conference on Trade and Development

estimates that almost 8,500 deadweight tons were carried by ship in 2010.

Incidents involving hazardous materials can be devastating to the well-being of individuals, property, and the environment. As delineated by the Code of Federal Regulations, reportable incidents include circumstances in which a person is killed or receives an injury requiring hospitalization as a result of contact with a hazardous material during the transportation process. Additionally, if the general public is evacuated, a major transportation facility or artery is closed, or an airline is rerouted from its operational flight pattern, reporting is required. Incidents also include fire, breakage, spillage, or suspected contamination involving radioactive material, infectious substances, or marine pollutants. The government requires detailed reporting following such incidents and administers a database to track their occurrence.

Since 2003, 162,449 incidents involving hazardous materials were reported in the United States, with a total of \$709,802,927 in damages, 2,723 injuries, and 131 deaths. Breaking these down by mode of transport: 14,145 involved air incidents, 140,332 highway, 7,311 railways, and 661 water. In 2012, 26 percent of incidents occurred during transit, 4 percent during in-transit storage, 20 percent during loading, and 50 percent during unloading.

Both federal and international agencies create and enforce legislation designed to minimize the frequency and the scope of accidents related to the transportation of hazardous materials. When manufacturers and transportation companies correctly observe the regulations, incidents are less likely to happen or be severe. Unfortunately, some companies choose economics over compliance, and some countries and regions have more political will and political capital than others.

Legislation in the United States

The Hazardous Material Transportation Act (HMTA) was passed in the United States in 1975 to regulate the transportation of hazardous materials. This legislation gave the secretary of transportation regulatory and enforcement authority for intrastate, interstate, and foreign shipments. The Toxic Substances Control Act of 1976 gave the Environmental Protection Agency (EPA) authority to oversee the production, use, and disposal of chemical substances. Section 8 of this act subjects commercial

manufacturers of chemicals to a number of recording and reporting requirements, such as health and safety studies and incidents of adverse reactions experienced by employees working with chemicals. The EPA also issues rules regarding acceptable limits of exhaust emissions by commercial vehicles.

The Resources Conservation and Recovery Act of 1976 specified instructions for using, treating, and tracking hazardous waste. The Hazardous Material Transportation Uniform Safety Act of 1990 aligned and clarified preexisting local, state, and federal laws relating to hazardous material transport. Most recently, because of the potential use of hazardous materials in acts of terrorism, the USA PATRIOT Act of 2001 forbade states from issuing hazmat licenses to individuals who have not been vetted by the Department of Transportation.

The Pipeline and Hazardous Materials Safety Administration (PHMSA), a Department of Transportation agency, has two divisions. The agency generates and enforces guidelines to ensure that transportation by land, sea, air, and pipeline is operated safely, reliably, and responsibly. The PHMSA operates five regional agencies that employ inspection and enforcement staff who ensure industry compliance with safety regulations through regular inspections and investigations of hazmat transport personnel, equipment, and procedures. The PHMSA also operates a pipeline safety training center in Oklahoma City, Oklahoma. In addition to inspection and enforcement, the agency provides new and revised hazmat standards to promote safety and minimize threat to health, property, and the environmental; it also conducts research to develop best practices and offers grants to states for their own pipeline safety programs. The PHMSA's directives apply not only to pipelines but also to any carriers of hazmat. Some of the standards specify the appropriate transportation containers for the given hazardous materials. Others outline the required manifest, marking, labeling, and placards demanded for proper hazardous material communication. The PHMSA delineates required training areas for hazmat employees who load or unload material, perform maintenance on or prepare shipping containers, operate vehicles transporting hazardous materials, or prepare hazardous materials for shipping. These employees must undergo general awareness training,

function-specific training, safety training, security training, and modal-specific requirements training, although the source and format of the training remains at the discretion of the employer.

The PHMSA works closely with other agencies, including the Federal Aviation Administration, the EPA, the U.S. Coast Guard, the Federal Railroad Administration, and the Federal Motor Carrier Safety Administration to coordinate safe hazmat transportation. Additionally, other federal agencies have jurisdiction over aspects of hazmat transport, including the EPA, and, in the case of worker health and safety, the Occupational Health and Safety Administration (OSHA).

International Regulations

Internationally, hazardous material transport is governed by two agreements: the International Civil Aviation Organization Technical Instructions for the Safe Transport of Dangerous Goods by Air (ICAO TI) and the International Maritime Dangerous Goods Code (IMDG Code). Additionally, the United Nations Committee and Subcommittee of Experts on the Transport of Dangerous Goods (UN COE and SCOE) meet twice yearly to discuss and ratify changes to the UN Model Regulations on the Transport of Dangerous Goods. While the UN Model Regulations are not legally binding, they do serve to inform the laws of member countries and help provide consistency and understanding among countries.

Directive 2008/68/EC of the European Parliament and of the Council of 24 September 2008 on the inland transport of dangerous goods governs hazardous material transportation within the European Union. Based on international agreements, the directive covers air, land, and sea shipments to reduce risks of accidents and threat to safety, health, and property damage. Many other countries have specific legislation governing hazmat transportation, and a substantial number of those countries provide reciprocity to shippers.

In Canada, the Transportation of Dangerous Goods Act, 1992, outlines requirements for the shipment of hazardous material within the country. Some provisions include, similar to those in the United States, labeling requirements, emergency planning and preparedness, and recordkeeping; the act authorizes the Minister of Transportation inspection and enforcement authority and outlines

penalties for infractions of the legislation. The ministry includes branches that develop training programs and operate a 24-hour emergency line, as well as branches that outline expectations for transportation and that provide inspection, investigation, and enforcement. Canada, Mexico, and the United States also work together to develop emergency response protocols for hazardous waste incidents.

China's State Administration of Work Safety (SAWS) released a decree, "Measures for the Administration of the Registration of Hazardous Substances," which became effective in 2012. These rules expand previous regulations and require domestic companies to provide extensive reporting of hazardous chemicals used as well as to disclose chemicals imported into China by foreign manufacturers. The reporting requires companies to disclose information on chemical classification, hazardous properties, usage, and emergency and safety procedures. Furthermore, the rules outline an expansion of China's Catalog of Hazardous Chemicals to include 7,000 to 10,000 substances.

The regulations and regulatory bodies represented by the United States, Canada, China, and the European Union are representative of the diverse laws governing hazmat transport, and the partnership among the United States and Canada, as well as participation in UN efforts, demonstrates positive progress toward protecting the safety of the world's population. However, the piecemeal regulations in a global economy often leave cracks whereby some countries and regions experience a disproportionate burden of the costs of hazardous materials. Hazardous waste is a case in point.

Hazardous Waste

Hazardous waste, or discarded materials harmful to human or environmental health when improperly managed, represents a concerning subcategory of hazardous material transport. Hazardous waste was not regulated in the United States until the 1970s when Congress passed a number of statutes to oversee the generation, transportation, and disposal of hazardous materials. The need for such legislation was underscored by high-profile incidents illustrating the devastating health and environmental effects of improper management and dumping of hazardous waste.

Developing and poor countries and regions are particularly vulnerable to devastating effects of

hazardous waste disposal. In 2006, for example, hundreds of tons of hazardous petrochemical waste were illegally dumped in Abidjan in west Africa's Côte d'Ivoire, resulting in 10 deaths and over 30,000 illnesses. The waste had originated in Amsterdam and traveled on a Panamanian-registered ship managed by Probo Koala, a Greek-managed firm, and chartered by the Dutch company, Trafigura, which claimed that tests on the waste conducted before the ship set sail indicated no toxic materials in the waste. Negotiations between Trafigura and the participants resulted in a 2007 settlement with the Côte d'Ivoire government for \$171 million (152 million euros), a 2009 settlement for no more than \$45 million (33 million euros) with the people made ill by the waste, and almost \$550,000 (400,000 euros) in fines to the Dutch government.

Contemporary Debates

Two current debates pitting environmentalists against the oil industry involve the transportation of hazardous materials. The proposed Keystone XL Pipeline, which would take oil extracted from Canadian tar sands across the U.S.–Canadian border in Montana and extend southward to the Gulf Coast in Texas. While many of the issues go beyond transportation of the oil, critics of the XL pipeline assert that future leaks are inevitable, especially since the diluted bitumen of the tar sands oil has more acidity, viscosity, and sulfur than conventional oil, although the Alberta, Canada, government disputes the claim that bitumen is riskier to transport. With this mix, current models of pipeline strength are misleading.

The high number of pipeline leaks—hundreds each year of varying severity—including the 2013 Exxon Pegasus pipeline leak of 5,000 barrels of crude oil in a residential neighborhood in Mayflower, Arkansas, and the 2010 Enbridge Oil Spill that released more than 10 million gallons of oil into the Kalamazoo River near Marshall, Michigan—indicate the inherent risk in these pipelines. That the Keystone I pipeline has already received orders of corrective action from the PHMSA in a short time of operation casts doubt on the state-of-the-art technology used to transport tar sands.

Hydraulic fracturing (or fracking), in which natural gas is extracted from shale mineral deposits, also generates emotional and contentious debates within many regions of the United States. While many of

A tug pushing a barge bursts into flames after striking an oil pipeline near Bayou Perot, south of New Orleans, Louisiana, March 13, 2013. There are hundreds of U.S. pipeline leaks every year.

the points are outside the domain of hazmat transportation, fracking does require the transport of chemicals to fracking sites as well as the movement of wastewater from the sites. Because of a provision in the Energy Safety Act of 2005, fracking chemicals are exempt from EPA regulation. Many fear the transport of these unreported chemicals poses significant health, safety, and environmental risks. In April 2013, a truck carrying fracking chemicals was turned away from a local radioactive, hazardous waste facility with a 96-microrem radiation level, 86 microrem above the facility's accepted range. This incident provided evidence for opponents of hydraulic fracking who fear that lax regulations will harm humans and the environment.

Critics assert that the safety regulations regarding hazardous material are not keeping pace with the technological advances and accompanying challenges. With increasing globalization and development, managing hazardous material within

and outside national borders should be a priority for decision makers. Businesses, too, can benefit from a standardized set of requirements. Additionally, because the air, water, and earth do not observe national boundaries, ensuring safe transportation of hazardous materials is critical to the overall health and safety of humans and the environment.

Health Issues

The transportation decisions that are made on a daily basis determine far more than how quickly one may get from point A to point B; they can have social, environmental, and physical consequences that collectively influence the overall health of both individuals and communities. The health impact associated with an ever-increasing number of people traveling by automobile and a concomitant increase in annual vehicle miles traveled has reached epic proportions. Growing evidence is revealing the myriad adverse health consequences arising from such an auto-dominant landscape. Ranging from mild to severe, and even to death, the consequences of transportation decisions can impact both the individual as well as the collective. Furthermore, while the physical health of an individual is most closely associated with transportation choices one makes, there are potentially serious social and psychological repercussions as well. Though driving a personal automobile affords privacy and individual freedom, this transportation choice impacts not only the decision maker but a host of other individuals as well. Perhaps most obvious is the growing obesity epidemic, which stands as the fastest growing public health problem in the United States.

Automobile Travel

In the simplest of terms, research has shown that traveling in vehicles increases the odds of obesity whereas traveling by foot decreases the odds of obesity. Certainly the correlation between increasing vehicle miles traveled and increasing obesity is well documented. With the number of total vehicle miles traveled increasing by more than 200 billion miles during the first decade of the 21st century,

obesity rates in the United States soared. The adult obesity rate for men increased from 27.5 percent to 35.7 percent and from 33.4 percent to 35.8 percent for women. Currently, the national adult obesity rate stands at 35.7 percent and the child obesity rate at just under 17 percent. With more than 12 million children currently overweight, childhood diabetes is a serious and growing problem. While transportation choices can contribute to obesity, obesity can likewise affect transportation costs. Increased body weight necessitates more fuel be burned to transport the same number of travelers. For air travel, these fuel costs can run into the hundreds of millions of dollars each year. On the highway, it has been calculated that upward of 1 billion additional gallons of fuel are consumed annually due to overweight and obesity.

While obesity itself is a health concern, more problematic is its association with a host of additional diseases. Time spent in the automobile is shown to increase the likelihood not only of obesity but of heart attack, high blood pressure, and high cholesterol. Obesity has been likened to a "conveyor belt" that can lead individuals to experience a dangerous mix of obesity-related illnesses.

The Built Environment

A sedentary lifestyle where much time is spent in an automobile is a principal culprit in the obesity epidemic. Yet more than simply personal preference, use of the automobile has been necessitated by sprawling land use separated by rigid zoning codes and transportation planning that has set the automobile above all other forms of transport. As a result, people who live in neighborhoods with older or more "traditional" designs are noted for spending more time walking and in total physical activity than those who live in newer, more suburban landscapes. The post-World War II era represents a marked shift in land use and transportation planning policies, with the gridded streetscape replaced by cul-de-sacs and mixed land use replaced by single-use zoning. The sprawling design has rendered this new suburban landscape nearly unwalkable and necessitates use of the automobile for virtually all trips. As the suburban landscape has expanded, the percentage of children walking or bicycling to school has declined. Without question, the built environment has a significant impact on human health and behavior.

Pollution

Furthermore, per capita vehicle miles of travel also positively correlate with emissions of nitrogen oxide (NO_x) and volatile organic compounds (VOCs). In sunlight, these pollutants react to form ground-level ozone, which can contribute to shortness of breath and even asthma. Not surprisingly, sprawling, car-dominated communities are associated with significantly higher emissions of NO_x and VOCs than the higher density, more traditional neighborhoods.

These air pollutants are also linked to many other health concerns, including respiratory morbidity and mortality, cardiovascular disease, lung cancer risk, birth defects, and eye irritation. With the automobile as a way of life, motor vehicle emissions have become the largest and fastest-growing source of air pollution and greenhouse gases. Moreover, with highways typically routed through low-income neighborhoods, a disproportionate share of air pollution burdens the health of the poor and people of color.

Noise from highways and other transport sources, including air travel, is increasingly being recognized as an environmental health issue. Described as unwanted sound, noise can affect cognitive performance, as well as mental health, physiological function, and even hypertension and heart disease. Without question, transportation-related noise concerns are affecting the health and overall quality of life of a large and growing proportion of the population.

Accidents

Transportation systems are an integral part of the built environment but are fraught with danger. Not only associated with secondary or indirect health concerns, transportation-related accidents can directly lead to serious injury and even death. Motor vehicle crashes are responsible for more than 40,000 deaths and upward of 3 million injuries per year in the United States alone. The leading cause of death for U.S. teenagers, motor vehicle crashes account for more than one in three deaths in this age group. In recent years, upward of 3,000 teens have been killed and more than 350,000 have been brought to emergency rooms for injuries resulting from motor vehicle crashes.

An increasing concern in driving fatality is the rise of distracted driving. Contributors to distracted

driving include use of a computer, cell phone, or onboard or heads-up navigation systems. In the United States, upward of one in six fatal collisions is the result of a driver being distracted when operating a vehicle. By far the greatest danger of distracted driving results from texting while driving. Studies have demonstrated that drivers who text are 23 times more likely to crash as nondistracted drivers. Thousands of additional road fatalities in recent years have been attributed to rapid increases in texting volumes.

Alternative Transportation

Loss of life is unquestionably the worst outcome and greatest concern; however, the economic cost of traffic crashes is also not insignificant. Reaching more than \$150 billion annually in property damage and injuries, alleviating this economic burden is another motivating factor to improving transportation safety. In response, there have been increasing calls regarding the need to develop alternative transportation opportunities—including walking, bicycling, and mass transit—through a holistic approach to transportation management. More transportation options can help relieve traffic congestion, reduce accidents, and improve environmental health concerns associated with transportation.

In recent decades, there has been a growing recognition that pedestrian-oriented development can contribute to the mental and physical health of an individual. As a result, new communities are being designed and existing communities retrofitted so that they emulate traditional, walkable neighborhoods. This design promotes both safety and transportation equity as well. In a country with an aging population, a near singular dependence on the automobile will no longer be sufficient. As a result, transportation options that afford freedom while addressing critical health and safety concerns are now being implemented.

Heavy Rail Transit

Heavy rail is a significant component in the transportation network of the United States. It consists of electrically propelled cars that operate in a tunnel (subway), on elevated tracks, or on a separated right-of-way. The trains of four to 10 cars, with average overall speeds from 25 to 40 miles per hour, provide the highest passenger capacity of any mode of urban rail transportation, but it is also the most expensive. Heavy rail systems are generally powered by a high-voltage third rail. The necessity of protecting people and vehicles from this voltage mandates that the rail system be fully separated. The separation is the source of heavy rail's high performance and its high capital costs.

Heavy rail is the dominant transit system in major urban centers in the United States, with some systems built more than a century ago and others dating from the last half of the 20th century. Since the 1980s light rail systems have substantially outnumbered heavy rail systems, largely because the costs of heavy rail can range from \$100 million to over \$1 billion per mile.

The Historic Systems

The oldest heavy rail systems in the United States were built before World War II, some of them as early as the 19th century. These systems were

generally built by private companies and later taken over by local governments dedicated to keeping the systems in operation. The best known of the early systems is the New York City Subway.

A subway system of nine lines serving 27 stations opened for business at 7 P.M. on October 27, 1904. The receipts for the first day of operations totaled \$5,594.05, representing 111,881 nickel fares. The entire sum was donated to hospitals in the city. Calls for expansion were almost immediate, and in 1913 the city signed contracts for the construction of another 123 miles, using both public and private capital.

The first passengers rode Chicago's famous L on June 6, 1892, when 30 people rode the Chicago and South Side Transit Railroad from 39th Street to the Congress Street Terminal. Extension came quickly in Chicago as well. By 1893, when the World's Columbian Exposition opened in Chicago, service ran to 63rd Street and Jackson Park.

In 1897 Frank J. Sprague invented a multiunit train control system for use on the L that allowed multiple railcars to be fitted with motors and eliminated the need for locomotive-hauled trains in rapid transit service. Boston (1897) and Philadelphia (1936) also had systems in operation during the first decade of heavy rail use in the United States.

These early systems were constructed with stations placed close together in order to reach more pedestrian patrons. Speeds were slower, and cars were shorter, designed for the tight corners characteristic of the urban areas they served. On February 4, 1952, nearly 20 years after Philadelphia's heavy rail line began operation, the Cleveland Transit System broke ground for a new heavy rail system. Service began on March 15, 1955. The Cleveland system was an anomaly. The period after World War II saw the automobile become the major mode of transportation.

Although some of the older heavy rail lines continued to expand, mass transit generally was faring poorly. A subway planned in Cincinnati had its right-of-way commandeered for freeway construction. It would take a shift in federal policy before a new kind of heavy rail system would draw other cities into heavy rail construction.

The Modern Systems

Only 3.9 percent of Americans were using any form of mass transit to get to work in 1960, and

one-fourth of those were in New York City. In 1964, President Lyndon Johnson signed the Urban Mass Transportation Act, which authorized \$375 million in aid for the capital costs of transit projects, with each federal dollar to be matched with one local dollar. Presidents during the next six administrations stressed the importance of mass transit in modern America.

In 1974, President Gerald Ford signed the National Mass Transportation Assistance Act, which distributed federal funds by formula for the first time in order to ensure that funding was available to help meet the transit needs of all of America's urban areas. President Ronald Reagan signed the Surface Transportation Assistance Act of 1982, which provided for a portion of the federal motor fuel tax to be used for public transportation investments. The amount of tax collected was increased during the George H. W. Bush and the first Bill Clinton administrations.

The first system to be built after the increased availability of federal funds was the Bay Area Rapid Transit (BART) system serving the San Francisco Bay Area, which opened to passenger service in 1972. The \$315 million in federal capital grants BART received helped make it the system it was, but federal aid made up only 20 percent of the total \$1.6 billion invested in the system. The heavy rail systems built after BART and additions and modernizations to older systems in Boston, Cleveland, New York, and Philadelphia received 80 percent of their funding from federal sources.

The systems that followed were much more heavily dependent upon federal investment. The Washington, D.C., Metrorail opened in 1976, followed by the Metropolitan Atlanta Rapid Transit Authority (MARTA) in 1979. The size of new systems decreased in the 1980s as the costs of both construction and operation increased. MARTA is 48 miles long; Baltimore's Metro, built in 1983, is 16 miles long.

Miami's Metrorail, which opened in 1984, is 24.4 miles. Unlike the earlier systems, the modern systems are designed to give automobile drivers an alternative. The stations are farther apart, the speeds are greater, and parking lots at outlying stations are standard. The Los Angeles Metro Rail is the only heavy rail system constructed in the 1990s. The Tren Urbano (Urban Train) in San Juan, Puerto Rico, began service in 2004.

Heavy Rail in the Twenty-First Century

Heavy rail continues to carry more passengers than light rail. In 2012, according to the annual report of the American Public Transportation Association, 3,648,329 unlinked passenger trips were made on heavy rail lines, many times more than the 488,504 trips on light rail lines. But nearly 90 percent of the heavy rail trips were made by passengers on the five busiest systems: New York; Washington, D.C.; Chicago; Boston; and San Francisco. More than 60 percent, or nearly 2.5 million trips, were made by New York City passengers. Six of the 15 systems reported fewer than 20,000 passenger trips for 2012.

Although existing heavy rail systems continue to construct extensions, they do so at enormous costs. The BART San Jose extension, scheduled to be completed in 2014, carries an estimated cost of \$251 million per mile. Costs are even higher for the Washington Metro extension to Dulles Airport, the second stage of which is supposed to be completed in 2016—at an estimated \$268 million per mile.

Most staggering is the \$2.1 billion per mile for the Second Avenue Subway in New York, also scheduled for a 2016 completion date. These construction costs added to maintenance and operating costs, which are also more substantial for heavy rail, have led some experts to predict that the day of heavy rail systems is ending except for the nation's most densely populated cities.

Helicopters

Helicopters are the most common type of rotary-wing aircraft, which generate lift through the revolution of wings (rotor blades) around a mast. In the case of helicopters, these rotors are driven by one or more engines throughout the flight, and the rotors also provide multidirectional thrust. Rotary-wing aircraft, though limited in their passenger and freight capacity as a result of size limitations, have a number of advantages over airplanes.

For instance, because they take off and land vertically, they require less horizontal space in which to do so and can do so more quickly. Adjusting the direction of the rotors allows helicopters to quickly maneuver forward, backward, or sideways, as well as to hover. This combination, which allows them to operate from rooftop helipads, has led to their use in emergency services. Other factors, such as their maneuverability and their ability to fly safely at low altitudes, have made them practical for disaster response, police use, and search and rescue operations.

Origins

Helicopters are among the earliest type of flying vehicle that humans attempted to construct. Rotary-wing toys have been successfully flown since ancient times, and the seeds of some plants, including the tipu tree, maple tree, box elder tree, and gyrocarpus nut, have distinctive wings that cause them to rotate in the air in a manner similar to helicopters, which inspired many early designs long before the physics of flight were well understood. The most famous designs are those of Leonardo da Vinci, the Renaissance man who in the 15th century designed a rotary-wing aircraft whose mechanics were inspired by the screw, though he seems never to have constructed his flying machine.

The word *helicopter* was coined in the 19th century, when Industrial Revolution engineers experimented with various forms of heavier-than-air vertical flight at a time when lighter-than-air flight in the form of hot air balloons had captured the popular imagination. Successful helicopter flights were made in the first decade of the 20th century, around the same time as the first successful airplane flights. Further developments were slower to come, and the helicopter industry did not really begin until the late 1930s. Both Germany and the United

States developed helicopters for military use during World War II, with the latter effort leading to the Sikorsky R-4, the first mass-produced helicopter, released in 1942.

Innovations

The R-4 used the rotor configuration that has become standard in the industry, consisting of a single, centrally positioned, lifting rotor (with three rotor blades) and a vertical tail rotor. Igor Sikorsky was the first to successfully use a tail rotor for antitorque, which has become part of the standard design for single-rotor helicopters. The tail rotor stabilizes the helicopter by generating thrust in the same direction as the rotation of the lifting rotor, which counters the torque created by the lifting rotor. The amount of antitorque created is controlled by pedals in the pilot's seat, which adjust the pitch of the tail rotor.

The tail rotor is one of the defining features of the modern helicopter and is important enough to safe flight that in most jurisdictions, and in the procedures followed by most aviation companies, it is one of the life-limited parts of the aircraft. Life-limited parts are routinely replaced with new parts after a predetermined number of flight hours, rather than relying on the subjective criteria of an inspection. Tail rotors, as well as elements of the drive system, are also inspected through fluorescent penetrant inspection (FPI) between replacement cycles. FPI is a chemical method of revealing—through use of a fluorescent dye—defects that would otherwise not be apparent in a naked-eye inspection.

The inspections require a skilled inspector to perform them, but apart from the labor cost they are cheap, fast, and effective. Helicopters are also generally equipped with a vertical stabilizer—a fin that helps keep the helicopter from rotating perpendicular to the rotors.

Some helicopter designs incorporate alternatives to the tail rotor, with some other means of countering the torque of the lifting rotor's rotation. Tipjets, for instance, mount the engine on the tips of the rotor blades instead of inside the helicopter's chassis and spin the rotor with small powerful nozzles. The jets may be afterburners, ramjets, or may use compressed air. By using tipjets to rotate the rotors, no torque is created, and no antitorque is required.

The principal difference between the early Sikorsky helicopters and modern helicopters is the engine type. Helicopters took longer to develop than airplanes because of their minimum engine requirements and the difficulty of generating enough power to create lift without adding too much weight to sustain flight. Sikorsky was the first to surmount the hurdle, using a piston engine design that is still used for some smaller helicopters. But in the 1950s an improvement was made, introducing a turboshaft engine that generated more power with less weight. Like a turbojet engine, a turboshaft is a gas turbine, but instead of producing thrust, it produces shaft power. Most helicopters today use lightweight turboshaft engines, which allow for faster flight and larger craft.

Regulations

While there are other aircraft capable of vertical takeoff and landing, helicopters are unique in their ability to hover for long periods of time. They can also maneuver and remain aloft at low airspeeds, which an airplane, for instance, cannot do. Helicopters can maneuver safely in areas airplanes are unable to access because of congestion or other dangers, and many of the uses to which helicopters are put take advantage of this, though it also poses regulatory questions. Because helicopters do not need as large a space for takeoff and landing as airplanes and are not as loud, Federal Aviation Administration (FAA) regulations concerning them are not as strict. However, businesses, residences, or medical facilities wishing to deploy helicopters from their property not only need the relevant licenses and permits but also need to ensure that their neighborhood is zoned for a helipad.

In many cases, specific routes are required of helicopter pilots (though requirements of this sort are often lifted in the case of search and rescue operations and other crisis response). For instance, the FAA and the New York State Department of Transportation maintain the New York Helicopter Route Chart, which consists of both suggested and mandatory helicopter routes, directing helicopter traffic along specific routes for the purposes of traffic management and public safety. Noise pollution is one of the leading concerns in helicopter traffic management.

There are also specific regulations pertaining to helicopter traffic at airports. At airports without

towers, helicopters are required to avoid airplane traffic and, like airplane pilots, they must announce their positions over radio using a common frequency. Because of their greater maneuverability and lesser runway needs, helicopter pilots are expected to pay attention to nearby airplanes and take pains to avoid them. At tower-controlled airports, air traffic controllers direct helicopter traffic, which may or may not be segregated from airplane traffic. While in flight, helicopters are subject to reduced visibility requirements compared to airplanes because they are more maneuverable.

Use

Helicopters are used for recreational flight and tourism, because their ability to fly low to the ground, hover, and fly slowly is well suited to sightseeing; for aerial observation, including surveillance and mapping, though smaller automated rotary-wing craft and drones are often used for this purpose today; for search and rescue operations; for fast transport in the military, during evacuations, and transfer of medical patients; for cargo transport; in firefighting, to deploy water and fire-extinguishing substances; and in construction. Aerial cranes are helicopters that carry loads via slings or cables, and they are the ideal means, in some cases the only practical means, of installing certain types of equipment on high places, such as rooftop equipment or mountain-top radio towers.

Helicopters, Emergency Response and Law Enforcement

As more dramatic examples of what can occur during otherwise routine workdays for emergency response helicopter crews, New York Police Department (NYPD) helicopters plucked passengers from the wing of Captain Chesley Sullenberger's downed U.S. Airways flight 1549 in the Hudson River on January 15, 2009, and a Los Angeles Police Department (LAPD) helicopter found lost hiker Danny Kim in the Angeles National Forest on January 13, 2013.

In the 2010s, approximately 800 law enforcement air support units operated in the United States and a comparable number in Europe, Asia, Australia, and other parts of the world. In the United States, local, state, and federal agencies use helicopters to support their missions, ranging from one helicopter in a local police department to the large helicopter fleets of the Federal Bureau of Investigation, the Drug Enforcement Administration, and the U.S. Customs Agency. Law enforcement air support units have grown so numerous that the Federal Aviation Administration (FAA), which has the responsibility of overseeing them, is sometimes hard-pressed to keep pace with its regulatory and enforcement responsibilities.

Even small states like Delaware have law enforcement rescue units; the Delaware State Police Aviation Unit performed approximately 2,000 missions in 2011. In May 2011, the Delaware unit answered an emergency call from the captain of the Greek tanker *Cosmic*, who reported that one of his crew members had fallen 20 feet and injured his head. The Delaware Air Rescue Team helped package the crew member, hoist him into the helicopter, and transport him to a hospital on shore.

Special Rescue Qualifications

Helicopters bring unique operating characteristics to law enforcement air support units. The helicopter's ability to take off and land vertically and its hovering capability give it a major advantage over fixed-wing aircraft. Because helicopters can hover, they can reach crevices and other places that are inaccessible to fixed-wing aircraft and other machines to rescue trapped people. Often helicopters come

equipped with winches that enable them to lower materials, move heavy objects, or lift injured people to safety. Technological advances, including no-tail rotors, night surveillance equipment, and quieter engines and parts, make the helicopter state-of-the-art effective.

Helicopters in law enforcement units rescue hikers stranded on mountains and in other places. The Phoenix Fire Department (Arizona) used a helicopter to lift a dying hiker off Camelback Mountain. They lowered a basket on a rope from the helicopter, secured the patient in the basket, and began to hoist him up to the helicopter. The basket containing the stricken hiker dangled from a rope high off the ground, and as the helicopter crew began to raise the basket, the rotor blades started spinning so quickly that the crew had to lower the basket and bring it back up again. The helicopter crew said that the patient, who fully recovered, would have died if the Police Department had not used its helicopter.

New York, Los Angeles, and Chicago Fleets

The NYPD's Aviation Division operates a coordinated air-sea rescue program complete with helicopters and scuba divers based at Floyd Bennett Field in Brooklyn. In 1929, the NYPD founded an air rescue unit stocked with fixed-wing aircraft, but by 1948, the department routinely used helicopters instead of fixed-wing aircraft because they were so easy to maneuver in the sky. NYPD helicopters have rescued civilians trapped on the ice, spotted fires, chased speeding automobiles, and spotlighted cars from the air for ground patrol officers to capture.

During the January 2009 rescue of the passengers on U.S. Airways Flight 1549 from the Hudson River, NYPD air-sea rescue units pulled two survivors from the icy river and treated them for hypothermia. When Hurricane Sandy struck in October 2012, the NYPD helicopter No. 23 rescued five adults and one child, all Staten Island residents, trapped on rooftops by rising waters. (Helicopter No. 23 was named for the 23 NYPD officers who died in the Twin Towers on September 11, 2001.)

After the NYPD pioneered the first law enforcement rescue unit in 1929, word of the helicopter's utility and maneuverability quickly spread from the NYPD across the country. Los Angeles County in California bought its first helicopter in 1956. Los Angeles County used its first helicopter to

help patrol traffic on the city's freeways, but the county enlarged the helicopter's role during the 1965 Watts riots when they used it to spot problems and direct policemen to the trouble spots. In the 21st century, the LAPD maintains the largest police aviation unit in the United States, operating a fleet of 17 helicopters and a King Air 200 out of Hooper Memorial Heliport in downtown Los Angeles. LAPD police helicopters are used to rescue stranded hikers, transport people needing medical attention to hospitals, and pull people from burning buildings.

The Chicago Police Department's Marine and Helicopter Unit features two helicopters, technically trained personnel, and specialized equipment to conduct rescue missions. Its helicopters routinely rescue boaters and swimmers from Lake Michigan.

Regulating Helicopters and Their Units

More helicopter units in the air means more potential for accidents and more conflicts between overlapping law enforcement units and between private helicopter companies and law enforcement agency fleets. Established in 1972, Helicopter Emergency Medical Service (HEMS), consisting of for-profit and nonprofit agencies, grew 130 percent between 1995 and 2008. Accidents and competition between law enforcement agencies and HEMS also have multiplied, with media stories recording "patient wars" between police and other medical transport helicopters.

The FAA has broad authority and responsibility to regulate aircraft operations, to monitor the use of navigable airspace, and to establish safety standards for and regulate the certification of air personnel, aircraft, and air carriers. The agency establishes safe altitudes to protect individuals and property on the ground, and attempts to temper excessive aircraft noise. It also addresses helicopter safety issues like the impact of weather on takeoffs and landings, night operations, and controlled flight into terrain incidents.

From 2011 to 2012, the FAA documented problems with the Port Authority of New York and New Jersey's operation of airports, including JFK, La Guardia, and Newark airports. The FAA's report cited the Port Authority for failure to instruct its police departments to oversee its rescue and firefighting air units. According to the FAA, every day during 2011 and the first half of 2012, JFK failed to

A low-flying U.S. Customs and Border Protection UH-60 Blackhawk helicopter bears down on two trucks during operations near an air strip in the U.S. southwest in 2008.

ensure that rescue and firefighting personnel were adequately trained. The FAA levied a \$3.5 million fine against the Port Authority and, in a 25-page settlement with the FAA, the Port Authority agreed to create a separate chain of command and training for rescue personnel and firefighters. Whether fire and police department helicopter units should operate separately or cooperate or combine operations is a hotly contested issue and one that will endure as air space becomes more crowded and operating costs continue to rise.

The effectiveness of the FAA and its safety regulations can be political and divisive issues. The National Transportation Safety Board (NTSB) is an independent federal agency that is responsible for investigating transportation accidents, promoting transportation safety, and reviewing enforcement actions involving FAA aviation and mariner

certificates and civil penalty actions. Two different regulatory agencies, each monitoring the other, sometimes cause confusion, political maneuvering, and in-fighting.

Future Large-Scale Rooftop Rescues?

Regulatory agencies like the FAA are also compelled to deal with technological changes in equipment, but many law enforcement agencies are resistant to changes in equipment and policies. In 1980, when a fire broke out at the 26-story MGM Grand Hotel in Las Vegas, police and helicopter pilots spotted the smoke first and sent out a radio alert. Thirty public and private helicopters mobilized to move 300 people from the roof and, with the help of the police keeping order, they succeeded. Eighty-four people died in the MGM Grand fire, but the people on the roof survived.

Thirteen years later, a catastrophic event revived the rooftop rescue issue. Shortly after 9/11, a *Wall Street Journal* story recalled that on February 26, 1993, a terrorist bomb exploded in the basement garage of the North Tower of the World Trade Center, funneling thick smoke up through the stairwells. Police rescue helicopter pilot Greg Semendinger lowered two men on a rope to the roof and they cut down antennas to clear a landing area for the helicopters. The helicopters rescued 28 people from the roof. The story pointed out that after the 1993 bombing, the Port Authority of New York and New Jersey, owners of the World Trade Center, and the fire department did not plan for future helicopter rescues.

On 9/11 two police rescue helicopters hovered a few hundred feet away from hundreds of workers trapped on the floors above the fire in the North Tower of the World Trade Center. Greg Semendinger again found himself planning a helicopter rescue. One of the helicopters carried a 250-foot hoist that could transport as many as 10 survivors at once, and its three-man crew had special training for rooftop rescues. The police helicopter pilots swooped in, but none of the survivors reached the roof because of locked doors and a predetermined evacuation plan.

The controversy about stairwells, locked roof doors, and the New York Police and Fire Departments' disagreement about fire rescue methods still continues. The New York Fire Department's opposition to helicopter rescues coincides with

the American mainstream approach. Fire experts around the country concluded that evacuating people is the best course of action when fires break out in skyscrapers and it is essential to send people down the stairs, not up to the roof. They point out that smoke and flames tend to rise, and people can get trapped on roofs if weather or smoke conditions make it impossible for a helicopter to approach.

Los Angeles is one of the few major American cities that defies conventional wisdom and requires high-rise buildings to plan for aerial rescues by mandating developers to build helipads on all buildings more than 75 feet tall, or about seven stories. The Los Angeles Fire Department used helicopters to rescue people from the roof of the 62-story First Interstate Bank Building during the fire of May 4–5, 1988, after which the LAPD embraced helicopters and their fire rescue possibilities. The Los Angeles Fire Department eventually established its own six-helicopter rescue wing.

High Occupancy Toll Lanes

High occupancy toll (HOT) lanes are road traffic management schemes whereby single occupancy vehicles are allowed to use high occupancy vehicle (HOV) lanes through the payment of a toll. Interest in HOT lanes has grown in recent years, and

projects have been implemented in several cities in the United States. The use of HOT lanes has potential advantages in terms of reduced congestion and pollution. However, there are doubts regarding the financial viability of the schemes, as demand for the use of HOT lanes may be insufficient to generate the revenue required to finance the costs of implementation and operation. Critics have also questioned the equity effects of the projects, arguing that they benefit road users who have greater ability to pay.

High occupancy vehicle (HOV) lanes are usually open to vehicles with a minimum of two or three passengers. These lanes allow faster speeds than other lanes, reducing congestion and promoting carpooling. However, the lanes tend to be underutilized and as such they represent an inefficient use of road capacity. Public perception of this inefficiency also reduces the social and political feasibility of the implementation of new HOV lanes. High occupancy toll (HOT) lanes address these problems by extending the use of HOV lanes to vehicles with one or two occupants in exchange for a toll. The scheme is also known as managed lanes or express toll lanes. The last concept is also used to describe HOT lanes where all vehicles, including high occupancy vehicles, are required to pay a toll.

The toll is collected through electronic toll collection systems, charging automatically the owners of the vehicles registered in the system without requiring them to stop when entering the lane. The toll is usually variable based on congestion levels, either set at certain times of the day or adjusted in real-time based on traffic levels. In some cases, the use of the HOT lanes is free for all vehicles during off-peak periods. The use of these variable pricing methods facilitates the management of demand for the use of HOT lanes, ensuring an efficient use of the total road capacity throughout the day, while preventing congestion in the HOT lanes.

HOT lanes are typically implemented in large urban areas and address specifically the accessibility needs of commuters, aiming at a reduction of time in the journey to work. These lanes have fewer ingress and egress points than general purpose lanes, providing fast access from a selected number of residential areas to the central business district (CBD) or other areas with high density of employment or services.

The QuickRide scheme in Houston, Texas, was one of the first HOT schemes, allowing vehicles

with two passengers to use HOV lanes during the peak period in the Katy Freeway. The scheme was introduced in 1998 and has since been expanded to other freeways. Similar projects have been implemented in other urban areas in the United States, with special incidence in California. These projects are usually limited to a selected number of roads in each city. However, in the San Francisco Bay Area an entire network of HOT lanes is currently being developed. This network will be 500 miles long upon completion in 2035.

Benefits and Drawbacks

The introduction of HOT lanes has a potential positive effect on urban accessibility, as the reallocation of traffic reduces congestion in general purpose lanes and allows for higher average speeds in those lanes without affecting speeds in HOT lanes. The implementation of HOT lanes also has advantages in terms of environmental quality, as the vehicle idling time on congested roads tends to be related to higher fuel consumption and higher emissions of local and global air pollutants. However, this positive effect may be canceled if many users respond to the implementation of the scheme by shifting from carpooling to driving alone in HOT lanes, thus increasing traffic levels. In the cases where HOT lanes are newly built, there is also a negative environmental effect linked to the use of extra land or the construction of elevated sections.

The advantages of HOT lanes in terms of reduced congestion may not be fully realized if the scheme fails to attract enough demand. Although the use of the HOV lanes tends to increase after the introduction of the scheme, it has remained in many cases significantly below the targets defined by the operating agencies. This means that road capacity in HOT lanes stays underutilized and congestion in the general purpose lanes is still above the optimum.

The problem arises because road users can opt between the use of general purpose lanes and carpooling or driving in single-occupancy vehicles in the HOT lanes. The choice between these options depends on the toll charged and also on the characteristics of the trip, such as length, time of day, purpose, safety, and convenience. There is also an element of uncertainty affecting choice in the cases where the toll is determined in real-time, as users cannot know in advance the price they will pay

for the use of the lanes. Research shows that HOT lanes are mainly used by drivers traveling longer distances. However, most drivers seem to use the lanes infrequently, for example, when traveling to places where they do not go on a regular basis. A survey of the use of the QuickRide facility in Houston showed that users of the system make less than 2.5 trips per month in the HOT lanes.

While HOT lanes are an additional source of revenue for transportation agencies, there are doubts regarding their long-term financial viability. The cost of implementation of the scheme is variable, depending on whether it involves the construction of new lanes or only the adaptation of existing HOV lanes. However, in the cases where demand is low, the system may not be financially sustainable if revenues are insufficient to cover operating costs.

There is also a high degree of monthly and annual variability in revenue, depending on macroeconomic variables (such as employment and income) and on environmental conditions (such as weather). A variety of funding and operating systems have been adopted, usually involving a mix of public and private capital. In the cases where the system is not financially sustainable, the system can be adapted by charging all users of the lane, including single-occupancy vehicles.

As with other road pricing schemes, there is also a social equity dimension to the effects of HOT lanes. Analysis of the socioeconomic characteristics of users of HOT lanes usually shows that individuals who are younger, single, and have lower income, lower education levels, and belong to racial minorities are less likely to use the system. Critics argue that because these groups have lower ability to pay to use the lanes, they are not provided with a choice to avoid congestion and are therefore at a disadvantage compared to other road users.

High Occupancy Vehicle Lanes

High occupancy vehicle lanes (often called HOV, diamond, or carpool lanes) are special lanes that give priority to high occupancy vehicles such as carpools and buses. HOV lanes are used to combat congestion, increase person throughput, improve air quality, and reduce fuel usage by encouraging drivers to carpool or use transit. Most HOV lanes are found in the United States and Canada, although Australia, New Zealand, and a few European countries have experimented with HOV lanes.

Classification of HOVs and HOV Lanes

The number of passengers necessary to be classified as a high occupancy vehicle (HOV) varies among and even within cities. At minimum, a high occupancy vehicle must have two or more passengers per vehicle; this is called an HOV2+ requirement. Other areas have three or more passengers per vehicle, or HOV3+ requirements. Finally, some areas restrict HOV lanes to buses and emergency vehicles only. Exceptions to these policies vary: motorcycles, two-seater vehicles, and taxis are often exempt, for example.

HOV lanes may have different definitions of HOVs, depending on the time of day. For instance, a lane may be HOV3+ during the peak period but HOV2+ or open to all vehicles during nonpeak periods. HOV lanes may also adapt to traffic patterns by being reversible lanes. Reversible lanes allow HOVs into the city in the morning but reverse directions

to allow HOVs out of the city during the evening rush. Reversible lanes may be exclusive HOV facilities that are physically separated from the general-purpose lanes or they may be contraflow lanes that are generally found in the median of the road and use lanes in the off-peak direction for HOVs traveling in the peak direction.

A dramatic example of contraflow lanes are the “zip lanes” that use special trucks to move a flexible barrier from one side of the road to the other in order to make space for HOVs in each direction. Zip HOV lanes can be found in Boston and Honolulu. Concurrent HOV lanes are lanes that are not physically separated from the general-purpose lane. They usually involve signage or paint striping to communicate they are for HOVs only. Some HOV facilities are simply on-ramps for congested areas or on-ramps with signal priority for HOVs. New HOV lanes may be added to the highway by converting a general-purpose lane or building a new additional lane. The distinction between a converted lane and an additional lane is important for understanding the impacts of HOV lanes because an additional lane adds to the traffic capacity of a road network and is more likely to create an increase in vehicle miles traveled (VMT).

Effectiveness of HOV Lanes

No consensus exists on the success of HOV lanes or even what criteria should be used to evaluate success. Many studies look at traffic-oriented outcomes, such as average vehicle occupancy (AVO), person-hours of travel, variability in person-hours traveled, the number or percentage of people carpooling, person-miles traveled, parking revenues, vehicle miles traveled, and travel costs, while other studies use economic welfare criteria such as compensating and equivalent variation and/or consumer surplus. Yet another aim of HOV lanes is to reduce air pollution and fuel usage. This may be accomplished by reducing the number of vehicles, by maintaining the number of vehicles but reducing the amount of stop-and-go traffic, and by using HOV lanes to encourage the adoption of zero- and low-emission vehicles.

HOV lanes encourage carpooling and discourage solo driving but that does not mean the net impact and the long-term impact is less congestion—the responses of other drivers need to be considered as well. If an HOV lane encourages solo drivers to carpool, other drivers may use the newly cleared

Automobiles enter a high occupancy vehicle (HOV) lane defined by paint striping on Ontario Highway 404 in 2010. HOV violation rates vary widely: In Tennessee, 45 to 85 percent of vehicles in HOV lanes have been in violation, while in Washington State, rates have been between 1 and 7 percent.

road space. This well-documented phenomenon, where drivers respond to the additional supply of road space by driving more, is called induced demand. Additionally, HOV lanes may draw users not only from the general-purpose lanes but also from transit, from not driving, and from alternative routes as well. This occurs especially if the HOV lane provides large time savings. Thus the number of carpools needs to be decided within the model (or endogenously), preferably as a function of the time and monetary costs of carpooling versus other modes of transportation.

The best studies account for the impacts of HOV lanes by using a traffic model to simulate the road network with and without HOV lanes. The best models allow for endogenous carpool formation and induced demand, and of those studies, half find HOV lanes increase traffic volume and the others

find that HOV lanes decrease traffic volume. Furthermore, the long-term impacts of HOV lanes are unknown, and there is reason to believe HOV lanes encourage sprawl by favoring longer commutes over urban roads.

HOV Lanes and the Environment

The 1990 U.S. Clean Air Act Amendments actively encouraged the building of HOV lanes by treating HOV lanes as an environmental tool. Through the Clean Air Act, the Environmental Protection Agency designates areas as nonattainment if they exceed federal air pollution standards. Nonattainment areas cannot build new highway or rail lines if they create or contribute to violations of the National Ambient Air Quality Standards. Nonattainment areas can build new HOV lanes because HOV lanes are considered a traffic control management measure. Thus, even though the impact of HOV lanes on traffic and air quality is unknown, HOV lanes are legally considered an environmental protection measure. There may be good reason for this. Even if HOV lanes do not decrease VMT, they may improve traffic flow and reduce idling, which can improve air quality. The long-term impacts of this are unknown and if induced demand effects are present, congestion may return. There is anecdotal evidence that HOV lanes are a compromise between environmentalists who want to reduce VMT and progrowth groups such as the American Automobile Association who would like to expand highways.

Public Support for HOV Lanes

The lack of consensus on HOV lane effectiveness in the academic arena is reflected in public attitudes toward HOV lanes. While the public seems to support many HOV lanes, some HOV lanes have been removed due to public outcry. The state of New Jersey removed HOV lane designations on I-287 and I-80 due to public protest. Florida converted Orlando's HOV lanes to general-purpose lanes due to high violation rates. If an HOV lane appears to be unused while the general-purpose lanes are congested, the public may pressure authorities to convert the HOV lane to a general-purpose lane, a condition some call "empty lane syndrome."

One solution to empty lane syndrome is to convert HOV lanes to high occupancy/toll (HOT) lanes. HOT lanes allow HOVs to drive for free or a

reduced rate but also allow low occupancy vehicles to drive on them if they pay a toll. Another solution to empty lane syndrome is to allow hybrid, electric, or other low-emission vehicles to use the HOV lane without meeting occupancy requirements. Allowing hybrids or other green vehicles to use HOV lanes often comes with unintended consequences, such as reducing the incentive to carpool by slowing down HOVs or subsidizing driving for those who bought a hybrid vehicle without the incentive.

HOVs and Transit

Research indicates HOV lanes have synergies with other ride sharing programs such as guaranteed ride home service, employer-provided preferential parking, and ride share cost subsidies. While undocumented, HOV lanes likely have synergies with transit that can be viewed as another form of guaranteed ride home and adds to the flexibility of HOV lanes. Bus rapid transit (BRT), which provides faster bus service than traditional bus routes, is an excellent option for carpoolers. BRT routes can save time on their dedicated BRT lane and these bus systems can expand their range by using HOV lanes. However, HOV lanes also likely draw passengers away from transit since those likely to spend extra time assembling a carpool are also those likely to spend extra time taking transit.

HOV lanes often motivate the practice of "slugging," or casual carpooling. Slugging is a form of hitchhiking that benefits the driver—who can now use the HOV lane—and the passenger—who receives a free or reduced-price trip to work. Slugging from northern Virginia into Washington, D.C., for instance, allows drivers and passengers to save time and money using the HOV lane, while slugging from Berkeley, California, into San Francisco allows drivers to pay a reduced toll on the San Francisco Bay Bridge. Slugging is likely enhanced by the ability in both cities to take transit for the return trip.

Compliance and Other Controversies

Driving in HOV lanes without meeting the HOV requirements is typically punishable by a fine, although enforcement rates vary. The Tennessee Department of Transportation has found that between 45 and 85 percent of vehicles in the HOV lanes are violating the HOV restrictions. Violation rates are much lower in other areas, especially

Washington State, where they are between 1 and 7 percent, partially in response to the HERO program, which allows other motorists to report violations via cell phone.

Drivers have been caught with mannequins in their vehicles in an attempt to drive in the HOV lanes as a single occupancy vehicle undetected. HOV requirements have also been used as a soapbox to argue about who and what is considered a person. In 2005 a pregnant woman in Arizona was stopped for driving in the HOV lane. She fought the ticket with the argument that her unborn child constituted a second person, thus entering the abortion debate as to when a fetus is considered a child. The judge denied her request, concluding that the additional person needs to fill a "separate and distinct" space in the vehicle. Similarly in 2013, a man from Marin County, California, drove in HOV lanes with only himself and the articles of incorporation for a business he owned. When pulled over, he argued the concept of corporate personhood allowed him to drive in the HOV lane, thus challenging the Supreme Court precedent that likens corporations to people. This challenge was also rejected.

High Speed Highways

Many countries and regions today have highly developed systems of high speed highways used to transport goods and people safely and quickly across long distances. Notable examples include the U.S. Interstate Highway System and the International European Road Network. Investment in these highway systems has many purposes, including building a sense of national and regional unity, as well as facilitating the economic benefits believed to result from lower transportation times and higher speeds over long distances. However, some critics charge that the economic benefits are not always forthcoming and that, in the United States in particular, an emphasis on high speed highways has harmed urban areas and favored the automobile at the expense of other means of transportation.

United States

The idea for the U.S. Interstate Highway System dates back to a 1939 report (*Toll Roads and Free Roads*) to the U.S. Congress suggesting construction of a toll-free express highway network, and construction of such a national system of highways was authorized by the Federal Aid Highway Act of 1944. However, construction on the system did not begin until authorization of the Federal Aid Highway Act of 1956, signed into law by President Dwight Eisenhower (hence, the interstate system is sometimes called the "Eisenhower Interstate Highway System"). Roads in the interstate system are owned and operated by the states in which they exist, but in order to encourage construction, the federal government paid 90 percent of the costs and the states contributed 10 percent. The first section of the interstate to begin construction under

the 1956 law was in St. Charles, Missouri, and in 1992, the system as originally planned was completed. However, roads continue to be added and improved. The Interstate Highway System currently comprises almost 47,000 miles of roads.

The interstate system was designed to facilitate safe, high speed vehicle travel. Interstates are limited-access highways, meaning that one can only enter or leave an interstate through a controlled exchange rather than by an intersection, as is typical of slower-speed roads. Federal regulations also specify the width of lanes (12 feet) and shoulders (10 feet), and maximum grade (3 percent), and stipulate that interstates must be designed for safe travel at 70 miles per hour. Minimum bridge clearance was originally set at 14 feet, but this was raised to 16 feet for new construction or reconstruction in order to facilitate the transportation of large military equipment. Pedestrians, bicycles, and other nonmotorized vehicles are not permitted on most stretches of the interstate, although in some states bicycles are allowed to travel on the shoulder.

In a 1954 speech, President Eisenhower outlined the purposes of the proposed interstate system; these included improving road safety, reducing road congestion, boosting the economy, and aiding military and civil authorities in meeting the demands of a catastrophe or military emergency, including an atomic war. The safety standard was certainly met; innovations in roads and automobiles as well as changes in laws (for example, much stricter enforcement of drunk driving laws today than in 1954) have made automobile travel much safer in general, and despite the high speed of travel on interstates, their fatality rate was lower in 2004 (0.8 per million vehicle miles traveled) than the average for all U.S. roads (1.46 per million vehicle miles traveled).

It is more difficult to evaluate the influence of the interstate system on congestion, because patterns of land use in the United States have undergone dramatic changes since 1954. Some of this change was fueled by the creation of the interstate system, which facilitated the development of suburbs by making it possible to travel longer distances more quickly by automobile. Similarly, the economic effects are more difficult to assess, as discussed below. The military benefits are also less clear: certainly the military benefits along with everyone else by a national system of high speed highways, but the proposed benefits of providing quick evacuation

from major population centers have proven elusive. Instead, long traffic jams leading out of cities in the face of impending weather catastrophes have suggested that the interstates are not adequate for this purpose. Not considered among Eisenhower's points was the effect of the interstate system on urban life. This has been negative in many areas, according to some urban planners, as interstate construction has destroyed traditional neighborhoods, created blighted areas, and shifted the funding and planning emphasis away from public transit systems and pedestrian-friendly areas.

Europe

Transportation policy in most of Europe differs from that in the United States in that more resources are invested in public transportation, and a number of policy measures (such as high taxes on gasoline) make driving relatively more expensive. However, many European countries have well-developed highway systems, and the E-road system—a route designation system developed by the United Nations Economic Commission for Europe—makes long-distance international road travel easier. The E-road system (also known as the International European Road Network) was developed in the 1970s and is partly modeled on the U.S. interstate system; it uses consistent signage to identify roads by type (for example, reference roads, link roads) and direction (north-south or east-west). Roads designated as part of the Euroroute system, an international network (for example, the E5 runs from London to Istanbul), are required to meet certain design standards to facilitate safe high speed travel, including specified speeds, maximum gradients and minimum radii for curves, and visibility standards to allow for safe minimum stopping distances.

The best-known high speed highway network may be the *Autobahn* (“highway”) system in Germany, which has no general speed limit, although certain areas such as curves and construction zones do have posted limits, and there is a recommended speed limit of 130 kilometers per hour (81 miles per hour) for automobiles and motorcycles. The roots of the *Autobahn* lie in the AVUS (*Automobil-Verkehrs- und Übungsstrasse*, the “trial automobile traffic road”) in Berlin, a two-lane divided highway completed in 1921. During the Nazi period, the national high speed road was expanded as part of a national propaganda effort, and expansion of the

system accelerated from the 1960s onward, comprising a network of almost 8,000 miles by 2007.

Economic Effects

National and international high speed highway networks may include privately built roads (for example, some toll highways in the United States), but most of the funding for these systems, including the planning and policy making regarding road construction, routing, and so forth, generally comes from government sources. There is a general assumption that investments in highway infrastructure pay off economically, primarily by facilitating economic growth, but this proves to be a difficult question to examine on a macro level because of the broad reach of a highway network and the different economic circumstances of the regions through which it passes. Given the budgetary constraints experienced by many governments currently, the inevitable competition for government investment, and the sometimes politicized nature of the debate, it is worth considering whether the ruling assumption that investments in highway infrastructure yield productivity benefits and whether there are ways to identify how and where money invested in highway infrastructure will yield the greatest benefits.

Howard Shatz and colleagues conducted a meta-analysis of research on the U.S. highway infrastructure at the national, state, and substate level and of highway infrastructure in other countries. They found that studies at the national level tended to find strong productivity effects and rates of return for highway construction, mainly by lowering transportation costs for industry. Some studies at the state level also found positive economic effects, although generally at a lower level, while other studies found no effects or negative effects, particularly when considering the economy of neighboring states. At the substate level, results were even more mixed, with studies finding positive, negative, or no effects for the area where the investment was made, as well as in the surrounding counties or metropolitan area.

They also found several factors that were related to the success or failure of investment in highway infrastructure in specific locations, in particular that benefits are reduced if a nearly complete transportation network is already available, and that benefits are related to the condition of the infrastructure and the current level of congestion. In addition, they recommend that the economics of relatively large regions

be studied, because a benefit may accrue to the area directly related to the new highway while surrounding areas suffer, a result that does not necessarily lead to greater overall benefit, and that cost–benefit analysis be used to determine not only if there was a benefit but whether the benefit was worth the cost.

High Speed Rail, Design and Technology of

The increase in air travel during the 1960s and 1970s coincided with a large downturn in passenger travel on railways worldwide. As the luxury and novelty of air travel increased, railways were under growing

pressure to stop the hemorrhaging of passenger losses. Their answer took the form of high speed rail. But have the design and technological advancements in high speed rail been sufficient to win back the passengers and attract new ones to use the service?

High speed rail differs from conventional rail service in that it is a rail transport system that operates at a much higher speed than conventional rail travel and uses a dedicated track with its own specialized rolling stock. These trains run on standard-gauge tracks of continuously welded rail on a grade-separated right-of-way incorporating large turning radii in the design to combat the high speeds reached when traveling around curves. While high speed rail is usually designed for passenger travel, some high speed rail systems allow freight to be moved over their lines as well.

Origins

High speed rail development began in 1899 in Germany when a 17-mile (27-kilometer) stretch of railway line between Marienfelde and Zossen was electrified. Speeds of 130.6 miles per hour (mph; 210.2 kilometers per hour [km/h]) were reached using prototypes in October 1903, demonstrating that high speed rail travel would be feasible. However, it was more than 30 years later when regularly scheduled high speed rail travel was introduced between Hamburg and Berlin. Development continued until it was halted by the outbreak of World War II in 1939. The United States entered into high speed travel with the Zephyr service in 1934, running a regular route between Kansas City, Missouri, and Lincoln, Nebraska, with top speeds of 115 mph (185 km/h) and this was quickly followed by other services, although top speeds were much lower than the Zephyr.

Most European countries looked at high speed travel during the 1930s and Great Britain, in the form of a streamlined steam locomotive called “Mallard” achieved the official world speed record for a steam locomotive at 125.88 mph (202.58 km/h). However, time-consuming maintenance issues meant that the days of steam for use in high speed were numbered.

Spain had a major breakthrough in 1945 with the development of a streamlined articulated train able to run on existing tracks at higher speeds than contemporary passenger trains. The Tren Articulado Ligero Goicoechea Oriel (Talgo) system used a unique axle system with one axle set per car end

connected by a Y-bar coupler. Among a number of advantages, the center of mass was only half the usual height. Today Talgo is the main Spanish provider of high speed trains.

In the late 1950s development proceeded with the passing of 187 mph (300 km/h) but not without some serious engineering problems to solve. It was noted that when trains traveled at high speeds, extremely dangerous hunting oscillation (the swaying of bogies) would occur, leading to dynamic instability and potential derailment. Yaw dampers were invented and used to solve this problem, enabling the speed of 187 mph to be reached safely. “Current harnessing” remained a problem until a solution was discovered 20 years later by the French TGV high speed rail service.

At the same time, in Japan, congestion on both road and rail had become a serious problem. Not wishing to import petroleum for security reasons, Japanese railway engineers looked at the development of a high speed regular mass transit rail service to efficiently move its 45 million people around the country. The Shinkansen (meaning “new trunk line”) was born after 10 years of development and trials and reached speeds of 130 mph (210 km/h) with an average speed of 101.2 mph (162.8 km/h) between Tokyo and Osaka. Speed was one part of the equation; the Shinkansen was also a form of transport that could be used by the masses. The “bullet trains” initially had 12 cars, later increasing to 16 before double-deck trains increased capacity further. Over 10 billion people have used the Shinkansen—without a single fatality.

1960s and 1970s

The 1960s saw countries in Europe developing their own high speed rail, which led to a revival in rail travel in some countries. France was at the forefront of this with the creation of the Aérotrain, a hovercraft monorail train that reached speeds of 125 mph (200 km/h) and went on to reach speeds of 270 mph by 1974 in prototype phase. This was followed by the French National Railways, which in 1967 fitted the Paris–Toulouse line with new signal systems, curve revision, and an onboard “in-cab” signaling system so that trains could reach speeds of 125 mph.

The United States was not to be left behind, and the High Speed Ground Transportation Act of 1965 was passed to create a regular high speed service between New York and Washington, which reached

speeds of 120 mph (192 km/h), faster than the Acela Express trains operating between New York and Washington in 2012.

In the 1970s British Rail, the railway network of Great Britain, introduced a new high speed service that reached speeds of 125 mph (200 km/h), hauled by diesel-electric train sets. It was the fastest diesel-powered train in regular service in the world and was built with a reversible multicar set having driving power-cars at each end. Journey times were reduced considerably and passenger numbers soared.

France continued to develop its technology and design of high speed rail and saw the use of gas turbines as a means of achieving the power required to operate the trains. This was used on a prototype involving an undividable set of five cars and two power-cars at each end, each power-car powered by two gas turbine engines. This prototype also used Jakobs bogies, which were shared by two cars to reduce drag and increase safety.

These developments continued until the French railways (SNCF) placed an order for 87 TGV Sud-Est train sets. This definitive train combined the various designs and technologies of the previous decade, resulting in an undividable set of eight cars, sharing Jakobs bogies, and hauled by two electric power-cars, one at each end. In 1981, the first section of the new Paris–Lyon high speed line was inaugurated with a top speed of 168 mph (270 km/h).

Recent Developments

Over subsequent years and with the advancement in technology and design, speeds of 237 mph (380 km/h) in 1981, 320 mph (515 km/h) in 1990, and 358 mph (574 km/h) in 2007 have been reached. With these top speeds, a new dedicated high speed line and complete capability with the existing network, the TGV can link every major city in a shorter time than before. This has led to air traffic on some of these routes decreasing or disappearing altogether.

Germany and France have continued to embrace high speed rail, with Germany developing a train similar to the French TGV, with streamlined motor cars at each end and a variable number of trailers between them. However, these trailers have the classical two bogies per car, allowing cars to be decoupled. Spain now has the largest high speed rail network in Europe and second only to China in the

world, after announcing in 2005 an ambitious plan to have 90 percent of the Spanish population living within 50 kilometers of a high speed rail station.

The United States abandoned high speed rail after its initial foray in the 1960s, and it wasn't until 1993 that the United States began to take note of the popularity of high speed rail travel in Europe and China. The Acela Express made its debut in 2000 on the Boston to Washington line, linking these cities with New York, Philadelphia, and Baltimore. This service operated at a profit, but unlike other high speed rail services, it lacks a dedicated line.

High speed rail was high on the political agenda in 2008 but no projects have yet commenced and are unlikely to do so before 2016. The California Proposition 1A (2008) approved the California High-Speed Rail network, but work on this project has yet to start nearly five years later. In 2012 the president of Amtrak proposed a \$151 billion dedicated high speed rail line between Washington, D.C., and Boston but it would take 25 years to fully design and build the line.

The greatest expansion in design and technology of high speed rail has occurred in a number of east Asian countries. Japan, South Korea, and China have embraced high speed rail and have taken it to another level.

South Korea launched its first high speed rail line in 2004 between Seoul and Busan, the two largest cities. Construction began in 1992 and the first commercial service launched some 12 years later. The top speed for trains in regular service is currently 190 mph (305 km/h), though the infrastructure has been designed for speeds up to 220 mph. Subsequent developments have seen speeds of 262 mph (421 km/h) achieved on other lines.

China has come rather late to the scene regarding high speed rail, with initial interest beginning in the early 1990s, but it has embraced the concept of high speed rail and has been busy expanding the service across China. The original aim of the Chinese Ministry of Railways was to research and develop domestic technology of high speed rail to a world standard. China successfully created a train set that operated at 300 km/h but it suffered poorly in regular service. To overcome this problem, it purchased high speed trains from French, German, and Japanese manufacturers, together with technology transfer contracts to improve its own ability.

As of 2011, China had the world's longest high speed rail network with over 8,300 kilometers of track that is still being increased with the intention of creating the 4+4 National High Speed Rail Grid by 2015. China also has the longest high speed rail line between Beijing and Shenzhen, covering a distance of 1,372 miles (2,208 km).

Design

Track for high speed rail networks is usually of a continuous welded type of rail, which is the most effective for reducing track vibration and misalignment. The continuous welded track usually rest on traditional sleeper and ballast, such as the French high speed lines, or on concrete tiles as is the case with German and Chinese high speed lines. The most common track gauge for high speed rail is 1435 mm standard gauge.

Almost without exception, high speed lines are electrically driven via overhead cables and have in-cab signaling, all developed over the previous decades. Advanced switches are also used, using very low entry and frog angles. High speed rail lines are efficient forms of transport movement as constrictions, such as at grade-level crossings, are eliminated. Japan and China typically construct their high speed lines elevated from road level, which allows for safe high speed travel at a much lower cost.

Another design feature of high speed rail is the avoidance of sharp curves, allowing for much higher speed limits. Curve radii are usually above 2.8 miles (4.5 km) with radii of 4.3 to 5.6 miles (7 to 9 km) for lines capable of reaching speeds up to 220 mph (350 km/h). On high speed curves the outer rail is usually 150 mm higher than the inner rail to create a 1:10 banking angle.

To reduce any effects from the surrounding environment, trees are usually cut and removed in a large area away from the high speed line and fences erected to prevent animals and humans from walking on or across the tracks.

Technology

Modern high speed trains differ from the earlier form of high speed trains that had one or two locomotives with traction motors. These were often positioned at the front of the train as a pair or at the front and rear to better distribute the tractive forces.

The modern high speed trains now have traction motors in every car, giving better force distribution and more comfort for the passenger. The train can also accelerate and decelerate faster as the power is distributed over more axles as the powered wheels rely on friction between the wheels and rail to transmit power. High speed trains also carry dry sand, which is dropped in front of the powered wheels to increase frictional forces in the event of ice or wet leaves on the rail line.

On a typical 16-car train set there are 32 traction motors, so half of the axles are powered as each car travels on a pair of two-axle bogies. With each motor contributing 600 kilowatts (kW), or 800 horsepower, the entire train set generates 19 megawatts of installed power with energy consumption averaging around 0.08 kW-hour/mile/seat.

When high speed trains start to roll, they accelerate at 1.6 feet per second squared (f/s^2), which eventually increases to around 3 f/s^2 , the upper limit that passengers can feel comfortable with. Braking deceleration is also around 3 f/s^2 , which would result in a train traveling 200 mph taking about 2.4 miles to come to a halt.

Most high speed trains get electricity from overhead wires or catenaries using a pantograph. The biggest challenge with using pantographs to take power from the catenary is keeping the contact forces between the two within a certain range—not too much friction but enough contact to make a solid electrical connection. In icy conditions two pantographs are used, with the front pantograph knocking the ice off for the second one to make the connection.

High speed trains also feature regenerative braking, which uses the traction motors as brakes and generates electricity. This electricity can then be fed back through the overhead lines to power another train as this electricity cannot be stored on board the train and is rarely fed back into the grid. If the electricity cannot be reused, it is burned off in roof-mounted braking resistors—known as rheostatic braking—or the train switches over to friction braking.

The preferred method of braking for high speed trains is regenerative braking because it minimizes wear and tear and saves energy, but these trains also carry electro-pneumatic friction brakes outfitted with steel discs and sintered pads designed for big loads. High speed trains have two levels of

emergency brakes. The first level uses all forms of brakes onboard. The second level is used in the event of no electric power so only friction braking comes into play.

Aerodynamic technology is constantly developing, as up to 60 percent of the tractive force can be lost due to drag and friction. Aerodynamics also need to make the train stable due to the fact that as speed increases, the cross-wind stability decreases. The four main areas that are looked at aerodynamically are the lead car with its streamlined nose and body; spoilers on top and underneath the cars; stowing and deployment of the pantograph and fairings around the bogies (the underlying framework), between the cars, and covering the underside of the train. The fairings also prevent any damage to the wheels and axles from track ballast or small foreign objects that may be on the track.

Streamlined fairings on the roof-mounted equipment limit the sonic booms when entering tunnels, as well as cutting down on drag. A smoother streamlined roof cuts down noise as well. When high speed trains pass each other at around 190 mph (300 km/h) 91 decibels of noise is produced, but only 72 decibels is heard inside the car due to sound-dampening coatings on the inside skin of the car. There are also noise absorbers on each set of wheels as well as air-spring bellows between the bogie and car body to aid in the reduction of noise inside the carriage.

HVAC is another area that has undergone technological development. Extreme temperatures can affect electricity usage on high speed trains by up to 30 percent. To achieve minimum electrical wastage, air intake units are based on passenger occupancy, and before venting cabin air outside to keep air inside fresh, it is routed through heat exchangers to preheat or precool incoming air. This allows the HVAC equipment to reuse up to 80 percent of the energy spent cooling or heating the cabin air.

The cost of constructing a two-track high speed rail line has been estimated by the U.S. Government Accountability Office at \$50 million per mile, although this can vary depending on the type of train; whether the rails run through urban areas, underground, or empty countryside; and how many roads and other railways need to cross over or under the high speed rail line.

The overhead lines also need to be factored into the building costs, as well as the type of track the

high speed rail will use: ballast track or slab track. The more traditional type of track, ballast track has cross-ties between the rails that are kept in place by gravel (ballast), whereas the slab tracks mount the rails on concrete track rather than using ballast. Slab track costs more to build but is less expensive to maintain.

Annual maintenance costs on high speed rails vary, with a European study showing costs at \$140,000 per year per mile while a British study has the annual cost at \$493,000 per mile. The reason for the high costs is that as speeds increase, tracks need to be inspected more often and built to tighter alignment tolerances.

Has the design and technological advancement in high speed rail been enough to win back passengers lost to the airlines and attract new customers? With a reported increase in passenger usage on high speed rail lines, it would appear so. The advancement in design and technology in high speed rail over the last four decades has proven to be a good investment, along with the modern terminals and the ability to travel from the heart of one city to another without the need to drive to an airport, spend two or more hours in a terminal building, and then land at another airport requiring a taxi or other form of transport to get to the city. High speed rail has an exciting future ahead.

High Speed Rail, Policy and Planning of

High speed rail has experienced rapid development in many countries of the world in recent decades. The development of high speed rail is a systematic process that involves route and station planning, technology innovation or adaption, financing, and many other considerations. As part of the public infrastructure systems, the development of high speed rail projects must also be bound by regulations and policies. Planning and policy of high speed rail are inextricably linked.

Because of differences in national conditions, the planning and policies of high speed rail in various countries differ. This introduction covers the core issues related to high speed rail planning and policy. Planning and policies of high speed rail are discussed in the context of different countries, including both the high speed rail that is already developed in such nations as Japan, France, and Germany, as well as the high speed rail that is still developing in China, Spain, and the United States.

Overview

Planning and policy of high speed rail can be defined as all the arrangements of planning, legal policies, and regulations for high speed rail development. In general, the core of high speed rail planning and policy relate to three elements. The first element is location plans for the high speed rail route and stations. Location planning considers the geography and topography of routes and distribution of stations. The fundamental purpose is to avoid complicated geological terrains in order to reduce construction costs and ensure operational safety. In addition, the location planning of the high speed rail route and stations also considers economic efficiency and regional development.

High speed rail can only obtain economic efficiency when it is designed to serve regions with high population density where intercity travel demand is potentially high to justify its construction and operational costs. High speed rail also facilitates regional economic development when it is designed to link regions with labor markets and job opportunities. In order to achieve these objectives, criteria and standards of high speed rail route and station planning are usually addressed

explicitly in the form of high speed rail development policies.

The second element of high speed rail planning and policy relates to the question of how to develop and effectively utilize high speed rail technology. The review of different countries' high speed rail developments indicates that there are at least two strategies for the development of high speed rail technology. The first strategy is to establish and develop one's own technology through independent innovation. This approach is very costly to implement, requiring a large investment in research and development. Countries including Japan, France, and Germany followed this approach and developed their own high speed rail technologies. The second strategy, which is less costly, is to adapt and utilize other countries' technologies through purchase and transfer. Some countries may further re-innovate and localize high speed rail technologies through establishing joint-venture companies with foreign manufacturers.

The high speed rail systems in Spain, China, South Korea, and the United States are developed through this approach. Given the complexity of high speed rail systems, selecting a suitable development strategy is critically important. It affects the economic vitalities of many domestic railway-related industries and also has significant influences on the national economic development. Therefore, the development of high speed rail technology is a vital component of high speed rail planning and policy.

The third element of high speed rail planning and policy is financing. The development of high speed rail is not affordable for any individual or company. Instead, it requires a strong commitment of national financial support. Due to the different national public financial conditions, high speed rail financing mechanisms can vary substantially. Generally, public financial support is needed to ensure the success of a high speed rail project. Other mechanisms such as issuing bonds, bank loans, attracting foreign investment, and public-private partnership investment are also used as primary or complementary funding.

It is clear that the context of high speed rail planning and policy varies across countries in different time periods and for different projects. In order to better understand the similarities and differences of high speed rail planning and policies, the following discusses the experience of six countries:

A Central Japan Railway Company Shinkansen train glides on the Tokaido line in 2008. The Tokaido Shinkansen opened in 1964, making Japan's high speed rail system the first to be developed in the world. Its trains now carry more passengers than any other rail system worldwide, with a total ridership estimated at 5.3 billion on the Tokaido line since it opened.

Japan, France, Germany, China, Spain, and the United States. This includes those countries that have already developed and are utilizing high speed rail, such as Japan, France and Germany, and those countries still in the development phase of high speed rail development and implementation, such as China, Spain, and the United States.

Japan

Japan was the first country in the world to develop modern high speed rail technology and infrastructure. Although the Japanese high speed rail system was built through public investment, it has now been privatized. The high speed rail planning and policy in its early development was implemented by the Japanese National Railways (JNR), which was a state-owned company. Following World War II, Japan was eager to revive its economy. The development of a new high speed passenger railway connecting Tokyo and Osaka became the primary

concern of Japanese transportation leaders and politicians. The plan was regarded as a practical and implementable strategy intended to revitalize the most dynamic economic corridor in Japan.

Because of strong research and development (R&D) capabilities in railway technology as well as the effective lobbying efforts by Japanese politicians, the Tokyo–Osaka high speed rail project obtained up to 194.8 billion yen in public financial support in 1958, which was equivalent to approximately \$4.07 billion in 2010. Though the construction costs were later found to be double the original estimate, JNR was able to complete the Tokyo–Osaka Shinkansen passenger system with financial aid from Japanese government investment and World Bank loans.

France

France was the first country in Europe to develop high speed passenger rail. Similar to the Japanese experience, the French high speed rail planning

and development policies were not led by the state Department of Transportation but by the French National Railway Corporation (SNCF). During the late 1960s and early 1970s, SNCF began to research and develop its own high speed rail technology called *Train à Grande Vitesse* (TGV), meaning “high speed train.” In order to reduce the impacts of public financial cuts due to the French economic stagflation in 1973, SNCF made several planning adjustments to the first French high speed rail route connecting Paris and Lyon.

According to the revised plan, two-thirds of the rail line would be newly built and the remaining one-third would utilize the existing railway lines that were mostly located in urbanized city areas. The strategic adjustment later proved to be a success as construction costs were dramatically reduced and the passenger travel time between Paris and Lyon was also reduced from the original four and a half hours to only two hours and 40 minutes.

Germany

Germany is another nation that developed its own high speed rail technology. Despite being part of the European Union (EU), the German system significantly differs in high speed rail planning and policy from the system in France. These differences are mainly reflected in route planning and technological specifications. Because Germany is a federal state, high speed rail planning and development policies needed to take different political interest groups into account. Deutsche Bundesbahn (DB), or the German Federal Railways, has a more dispersed interest structure than that of its French SNCF counterpart.

For example, the initial German high speed rail route plans reflected the special considerations for regional balance of service distribution and rail investment. Instead of proposing an integrated new high speed rail route for the German Inter-City Express (ICE) trains, two segments of new infrastructure were planned and selected in both south and north: the Hannover to Würzburg ICE line would serve northern Germany and the Mannheim to Stuttgart ICE line would serve the southern region of Germany.

In general, planning and policies of high speed rail in Germany required the development of new infrastructure to connect more regions so as to serve a broader public, which normally has to constrain the advantage of fast speed.

In addition, unlike the centralized political system in France, high speed rail development in Germany was a compromise between various political groups and interest groups. As a result, the planning and policy of high speed rail had to coordinate and accommodate different views. For example, in order to satisfy the environmental groups and organizations, high speed rail planning and policy in Germany had to give greater consideration to environmental issues than Japan or France.

Inevitably, this increased construction costs because of the designs and applications of tunnels, viaducts, noise barriers, and other techniques to reduce the environmental impact. Further unlike Japan or France, the German system had to accommodate freight movement to a greater degree than the other two. This was important for support from manufacturers and export industries as well as for the federal states where these industries are concentrated.

China

China has the highest high speed rail mileage in the world after a decade of investment and construction. Unlike Japan, France, and Germany, high speed rail planning and policy is a governmental activity, which is the responsibility of the Ministry of Railways (MOR) of the People's Republic of China. The earliest planning and policy making for Chinese high speed rail was initiated in the 1990s. The MOR submitted the “Beijing–Shanghai High Speed Railway Program Concept Report” to the National People's Congress, which was the first proposed high speed rail development plan. With the rapid growth of the Chinese economy, the existing passenger rail service was not able to meet the exponentially increased travel demand. High speed rail development became necessary to expand passenger rail transport capacity.

In 2004, the State Council approved China's first Mid-Long Term Railway Network Development Plan, which proposed the idea of building four vertical (north–south bound) dedicated high speed rail passenger lines and four horizontal (east–west bound) rail lines to connect the country's major economic centers. The State Council later adjusted the plans twice, in 2007 and 2008, which ultimately expanded total high speed rail track length from 7,456 miles (12,000 kilometers) to 9,942 miles (16,000 kilometers).

Although China attempted to develop its own high speed rail technology at the early development stage, MOR later decided to develop the high speed rail system through acquisition of foreign technology. Chinese railway manufacturers collaborated with high speed rail manufacturers from Japan, France, and Germany to achieve high speed rail technology absorption, transfer, and localization. China also implemented a short-distance (18.95 miles) high speed rail from Shanghai to Shanghai Pudong International Airport using German maglev technology.

This was the first large-scale utilization of this technology for commercial operation worldwide. In terms of the financial concern of high speed rail planning, the major financial support was from the central government. Other financial sources, including local government investment, bank loans, foreign investment, and issuance of railway bonds were also widely utilized.

Spain

As of the end of 2012, the total length of high speed rail tracks in Spain reached 1,656 miles (2,665 kilometers). This makes Spain's high speed rail network the second largest in the world. Similar to China, there was significant high speed rail investment by the Spanish government. Spanish high speed rail development has been rapid and recent. The high speed rail network connects the capital city Madrid to several major cities such as Barcelona, Seville, Valladolid, Toledo, Albacete, and Valencia. The network also reaches to the French city Perpignan with connections to TGV, symbolizing the linkages with the European high speed rail network.

High speed rail planning and policy is managed by the Spanish Ministry of Transport. The high speed rail technologies are based on the French TGV and the German ICE experiences. The major financial source for Spanish high speed rail came from state revenue involving a number of administrative departments. In addition, Spain also received large European subsidies for high speed rail construction.

For example, the total cost of the Madrid–Valencia high speed line is 12.4 billion euros, of which 1.949 billion euros was from EU subsidies. Other high speed rail projects, such as the one connecting Madrid to the French border, received EU funding

of 3.389 billion euros. In addition to the central government and EU support, some regional governments also contributed to the high speed rail projects that serve their jurisdictions.

United States

Passenger rail service in the United States accounts for only a small proportion of the intercity travel market. Currently, there is only one so-called high speed train service—Acela Express—which is operated by the National Passenger Railroad Corporation (Amtrak) between Washington, D.C., New York, and Boston in the Northeast Corridor. By the definition of the Union of International Railways (UIC), it is a high speed rail as its top speed can reach 150 miles per hour (mph); however, due to the limitations of its obsolete track and signal systems, the service runs at lower speed during most of the sections. The planning and policy of U.S. high speed rail are not subject to sustained attention as in other countries. The main reason is the American democratic political environment as well as the dominance of highway and aviation within the transport system.

High speed rail development policies were seriously considered by the government only twice in U.S. history. The first time was in 1965 when President Lyndon B. Johnson advocated the development of a high speed rail line. Because of his effort, the United States experienced a period of high speed rail R&D in the late 1960s. As a result, two types of high speed train technologies, the Turbotrain and the Metroliner, were developed and served the northeast travel market for a period of time.

The second time was in 2009 when President Barack Obama took office. The American Recovery and Reinvestment Act of 2009 for the first time in the U.S. history allocated \$8 billion of public money to support research, planning, and construction of high speed rail. The support was extended as Congress allocated another \$2.1 billion in 2010. In accordance with the requirements of the Passenger Rail Investment and Improvement Act of 2008, President Obama officially announced the new plan for development of a U.S. high speed intercity rail program on April 16, 2009. The plan outlines priorities for 11 high speed rail lines.

The new plan suggests that a U.S. high speed rail service could serve 80 percent of Americans in the next 25 years. Although the high speed rail plan

was proposed with a series of objectives, such as stimulating economic development, reducing oil dependence, and promoting traffic efficiency, the U.S. high speed rail policy is also generally considered a political solution for job creation in a recession period. Long-term commitment is still uncertain.

High speed rail development in the United States faces many challenges. Similar to Germany, railway planning and construction in the United States are influenced by special interest groups, ranging from competing transport such as airlines to not-in-my-backyard (NIMBY) and environmental groups. Negotiation with these groups can be very challenging and time consuming. In addition, the lack of a sustainable and long-term financing mechanism makes high speed rail development hardly a reality for the United States in the short term.

High Speed Rail, Safety Issues of

Plans have been made in the United States to develop high speed rail (HSR), defined as intercity passenger rail service reaching speeds of at least 110 miles per hour. The U.S. Department of Transportation (DOT) High Speed Rail Strategic Plan 2009 proposes the creation and expansion of a network of high speed rail corridors in the country.

One of the strategic transportation goals in the plan is to ensure the safe movement of goods and people, a huge challenge given the ambitious nature of the plan. Moreover, in spite of the fact that regulations emphasize the importance of crash survivability, the issue of crash avoidance should take priority over crash survivability.

Railway accidents are a common occurrence, the causes of which range from drivers' errors (including excessive speed) to mechanical failures. Take, for example, the Chatsworth train collision in southern California in 2008, in which 25 people died. A safety backup system could have prevented the train from going through a red signal. Had positive train control (PTC) been used, the accident might not have happened. High speed trains have also been involved in collisions leading to significant fatalities. The Eschede train disaster in Germany in 1998 resulted in 101 people losing their lives.

Key Measures

In the United States there were several fatal rail accidents between 2002 and 2008. In response Congress adopted the Rail Safety Improvement Act of 2008 (RSIA), which constituted the first authorization of the Federal Railroad Administration's (FRA) safety programs since 1994. The RSIA requires the FRA to, among other things, develop new safety regulations. These regulations cover different areas related to railroad safety, such as hours of service requirements for railroad workers, positive train control implementation, standards for track inspections, certification of locomotive conductors, and safety at highway-rail grade crossings.

Crucially, the act requires the introduction of PTC systems on every main line that is used by intercity rail passengers or commuter rail passengers on a regular basis by the end of 2015. The PTC

systems are designed to react automatically to the emergency situations by slowing down or stopping a train. These systems are programmed to avoid the most dangerous situations, such as head-on collisions or derailments due to excessive speed.

The current safety standards depend on operating speeds. Thus, trains traveling between 80 and 90 miles per hour (mph) trigger the five lowest safety standards (classes 1–5) whereas the operators of the trains running at speeds over 150 mph must comply with the highest (class 9) safety standards and a special order that governs the operating systems. Trains running at the following speeds, 91 to 110 mph, 111 to 125 mph, and 126 to 150 mph must adhere to the class 6–8 safety standards, respectively. The current plans to develop high speed rail (HSR) systems running at around 110 mph may not require the highest safety standards.

Safety Standards Review and Development

The FRA's High Speed Passenger Rail Safety Strategy provides a good overview of the existing and planned safety standards. The FRA acknowledges that it is looking at the safety standards developed in Europe and beyond, where trains can travel up to 220 mph. It highlights that the American track system differs significantly from the systems in other countries. The former has been built primarily for freight transport whereas the European tracks serve primarily as passenger rail.

This difference poses a greater challenge for the U.S. stakeholders to develop HSR services. The FRA is also exploring other avenues for improving safety standards through its rulemaking. Crucially, in order to address the issue of prevention discussed above, the FRA is reviewing the preventive measures in place and the potential developments in this area.

Take, for example, a proposed staggered approach for PTC systems. Thus trains running at higher speeds will require more stringent PTC systems such as “fail safe” for trains operating at 90 mph or special preventive analysis for trains running at 125 mph. Moreover, in terms of prevention, the FRA is looking into vehicle track interaction, grade crossing safety, maintenance-of-way safety management, right-of-way safety, and real-time system monitoring.

The FRA is also looking at the mitigation of damage that might occur in emergency situations.

Currently, the Passenger Equipment Safety Standards distinguish between two tiers of equipment. First-tier equipment can be used in emergencies involving passenger trains traveling up to 125 mph and on the freight system. Second-tier equipment can also be used on freight systems passenger trains running up to 150 mph. The two-tier system has already been criticized by many stakeholders for not being failure proof and not adequate to be used beyond freight tracks.

Further, the agency is learning from outside U.S. operators who have tested and used highly innovative systems for predicting the survivability rates in different conditions and complementary risk reduction measures, such as signaling systems, that allow for the maximum levels of crash avoidance. The FRA is also looking at the distribution of passengers among cars and fuel tank integrity.

Speed-Neutral Requirements

Most of the safety standards address the prevention and mitigation of accidents, which are often perceived to be caused by speed. The safety standards also include the ability of emergency services to respond quickly to the emergency situations with maximum preparedness. Swift response can reduce damage and save lives.

There are a number of management systems developed by the FRA and the American Public Transportation Association's Passenger Rail Equipment Safety Standards Task Force in anticipation of HSRs. The agencies and other stakeholders are also working on system safety standards, which allow for the identification of safety needs and managing them over long time horizons.

Further, the speed-neutral measures are concerned with, among other things, the hours of service, specialists' training and certification, misuse of alcohol and drugs, and workplace safety. Some of these speed-neutral measures have also been identified as inadequate for HSRs.

The FRA established a Railroad Safety Advisory Committee (RSAC) in 1996 to work with all stakeholders in the rail community to develop new regulatory safety proposals. RSAC, including its specialist task forces, has been working on safety standards dedicated to HSRs. It has looked, for example, at the following issues: strategies for the disabled, emergency lighting, evacuation, luggage retention, and window glazing standards. Many of

these matters constitute speed neutral measures that must be reviewed, especially in anticipation of high speed rail.

Dark Territory Safety Enhancements

Dark territory is a term used to describe the railway track sections without installed or operational signaling and control system equipment. It is estimated that dark territories compose at least 40 percent of U.S. railway lines. Section 406 of the RSIA requires the secretary of transportation to “prescribe standards, guidance, regulations, or orders governing the development, use and implementation of rail safety technology in dark territory.”

The main task is to develop regulations to cover technologies such as remote-control switches, high water or earthquake detectors, and grade crossing video monitors. Currently, the RSAC’s Dark Territory Group is considering which type of regulation should be used for specific technology.

The main question is whether to use prescriptive regulation, often very costly at the implementation stage, or performance-based regulation that focuses on the desired outcome and may be costly at the initial stages of development and drafting. One possible scenario, presented unofficially by the FRA, is a mixed approach. Thus, a rule would cover each technology and would envisage voluntary participation in the use of the technologies.

The rule would be accompanied with guidance that would prescribe minimum requirements for each technology. The railroad operators would have to establish “dark territory technology plans,” to be approved by the FRA, in which they would explain how they intend to meet the minimum requirements specified in the guidance document. The FRA would subsequently audit the operators and hold them accountable for following their plans. It is not clear at this time whether this approach will be adopted formally.

High-Speed Rail Investment Act of 2001

The High-Speed Rail Investment Act of 2001 was introduced into the House of Representatives (H. R. 2329) on June 27, 2001, by Representative James Oberstar (D-MN), Chairman of the House Transportation and Infrastructure Committee and 124 other members. It was joined with S.B. 250. The bill’s proponents urged its passage as a way to urgently address highway congestion, which was costing the nation an estimated \$100 billion in lost productivity. The bill, when enacted, would begin the development of a system of high speed railways.

Railroads have been carrying passengers since the 1840s. From the 1850s to the 1950s they were the major form of overland transportation. The advent of interstate highways in the United States and super-highway systems designed to carry large volumes of passenger automobiles around the world has led to a decline in passenger train travel. However, new faster high speed train systems have been and continue to be developed for carrying passengers.

The high speed rail systems operate at much faster speeds than those used by older, traditional passenger trains. The newer systems used standard gauge rails that are continuously welded. The tracks are laid on a uniform railbed that has its own right-of-way and on curves has a turning radius that is not a threat to stability inside the train nor to derailment of the train from a failure to maintain the rails.

International High Speed Rail

In 1964 Japan opened its bullet train system that attained speeds of 100 miles per hour. However, improvements have allowed the speeds to gradually increase to much higher speeds. Called the Tokaido Shinkansen, it was operated by the Japanese National Railways (JNR). Since 1987 it has been operated by the Central Japan Railway Company (JR Central). Today it has the highest passenger volume of any train in the world. There are local trains in Japan, but these take much longer to go the same distances. The bullet train connects cities such as Tokyo and Osaka with rapid service, but the price of tickets for individuals is expensive. Many people purchase a rail pass that permits unlimited use. Others are supplied with tickets their company purchases as a business expense.

In more recent decades many countries have developed high speed rail lines that connect their major cities. The most prominent countries are China, France, Germany, Italy, Turkey, South Korea, Spain, and Taiwan. Today's high speed trains usually travel at maximum speeds of 185 miles per hour (mph). Most of the high speed rail systems are designed for passenger traffic; however, some high speed freight systems are being built, such as the French mail service, La Poste.

China is developing a national high speed rail system. It is accused of having stolen the technology for its systems from the company that builds the bullet trains in Japan. The system is connected to the Shanghai maglev system that runs from the airport to downtown Shanghai at speeds of more than 200 mph.

U.S. High Speed Rail

The United States was the world's leader in railroad development in the 1800s. Railroad companies, often with government land grants, created a huge network of rails across all of the country. However, by the 1960s most of the American railroad companies were abandoning passenger service for freight hauling. The great expansion of the Interstate Highways System and the higher levels of prosperity following World War II coupled with very cheap gasoline made automobile travel very easy and more affordable than other forms of travel.

A major factor in the end of rail service, including light rail and trolley service, was the purchase of streetcar companies and electric trains by the

General Motors Company in a conspiracy. In what is also called the Great American Streetcar Scandal, the General Motors Company sought to eliminate competition for its automobiles in U.S. cities. As a result, several generations of Americans grew up without any rail service experiences. However, by the end of the 20th century, the enormous increase in traffic and the distances commuted were creating traffic jams, driver fatigue, and environmental issues as ever larger highways had to be built. Consequently, many Americans began to reexamine travel by passenger train service.

In the United States, the federal government has defined high speed rail service as service that operates in excess of 110 mph. Only one rail line meets this definition—the Acela Express operated by Amtrak. It is slowed by the fact that it does not operate over a dedicated track but has to share it with conventional rail service on its Boston–New York City–Washington runs.

Plans for a high speed rail system in the United States have been circulating since the 1960s when the High Speed Ground Transportation Act of 1965 was adopted. The act was partly a response to the Japanese bullet train. One outcome was the New York–Washington Metroliner service. However, little has been accomplished since, although there are many plans for a system that would have trains moving at 220 mph on dedicated routes across the country.

The Act

In 2001 Congress passed the High Speed Rail Investment Act (HSRIA). The aim of the act was to help the National Railroad Passenger Corporation (Amtrak) raise funds for capital investment. Over the previous 30-year history of Amtrak, it had received over \$25 billion from the federal government, including an appropriation of \$521 million for fiscal year 2001. The cost of operating the line was not being met by revenues. Though its revenues had risen in recent years, its costs had risen even more, and it was not generating sufficient revenues to stay in business. So if Amtrak were to continue to provide rail service across the United States, and especially in the northeast urban corridor, it was necessary to provide federal financial assistance to pay for its operating and its capital maintenance and development costs.

The HSRIA authorized Amtrak to issue up to \$12 billion in “tax credit bonds” between 2001 and

2011. Tax credit bonds pay lenders in “tax credits” rather than interest. So when calculating the value of the bond, the bondholder calculates the impact of the tax credit upon its federal (and state if applicable) tax bill. The savings in taxes might well be more than the profit after taxes from interest on the bond so they are desirable to bondholders in high-income brackets.

The proceeds from bond sales would go into an interest-bearing trust account, however, those proceeds would have to be spent within three or four years to comply with the arbitrage provisions of the act. The Congressional Budget Office (CBO) analysis suggested that the account’s trustee would have difficulty finding investments that would provide a sufficient return to repay the principal.

The HSRIA bond money was to be used to pay for capital improvement projects that are dedicated to high speed rail. Most of these are in the Amtrak Northeast Corridor. Essentially, the HSRIA amended the Internal Revenue Code of 1986 to allow a tax credit to holders of qualified bonds issued by Amtrak. It also amended Title 49 of the U.S. Code to grant authority to the secretary of transportation to approve projects that would be funded by HSRIA tax-credit bonds.

Cost analysis of the HSRIA’s funding mechanism for a high speed rail system was unclear because the cost to build a high speed rail system in the United States is not known. The Northeast Corridor alone would cost at least \$100 billion. However, before the adoption of the HSRIA, the House of Representatives received a report it had requested from the CBO on the financial implication of the tax credit bonds. The CBO report considered only the financial implication of the funding and not transportation policy.

The CBO reported that the bond would have an impact of about \$7.4 billion in “present-value terms” (that is, the value of money in 2001). The states would also lose about \$1.8 billion in tax revenue on the bonds as a tax credit vehicle rather than a tradition interest-bearing vehicle. The total government cost would be about \$9.2 billion. However, the CBO expected the bond program would raise only about \$8 billion (in 2001 value) for Amtrak. This method of funding, the CBO concluded, would be 15 percent more expensive than simply funding Amtrak with \$8 billion in appropriations and matching state grants. Therefore, the tax credit funding method

would be a new approach that was more expensive than just outright federal assistance.

The bonds would mature in 20 years, but there were a number of other issues noted in the CBO report. The issues included the securing of buyers for the bonds, the security of the bond capital, and the possibility of changes in Amtrak’s future status creating unforeseen tax liabilities for bondholders. Another issue was the tax liability of income from the capital in the bond capital trust fund.

The CBO concluded that the bond program was also more expensive than the issuance of tax-exempt federal and state bonds with the principal repaid from government funds. It also concluded that the tax credit bonds would obscure the true cost of what was really a new spending program that would reduce tax collections, with the subsequent impact on federal and state budgets.

The CBO noted a major problem with the legal status of Amtrak. In theory it was a private company. A number of private railroad companies had common stock certificates of ownership that had been given to them in compensation for their track and rolling stock that had been taken when Amtrak was organized in 1970. However, the stock was essentially worthless, and even if there were any profits, the secretary of transportation, as the owner of all preferred stock shares, would be first in line to claim them. The plain fact, the report noted, was that Amtrak was financially dependent upon the federal government and would go bankrupt without its support.

The legal fiction of Amtrak’s “private ownership,” the CBO report stated, essentially kept it off-budget. Its entire board was appointed by the president with the advice and consent of the Senate. As its entire board was appointed by the president with the advice and consent of the Senate the “private company” label on Amtrak was at best tissue thin and far from reality.

The political fact was that the federal government has extensive control over’s Amtrak policies through its board of directors as well as through the leverage of its financial support. The legal status of Amtrak, and not the political reality, was what prospective bond buyers would want to examine. The “private” company status of Amtrak meant that the federal government would not be responsible for its obligations. Therefore, if Amtrak failed to repay the bonds, the federal government would not be liable,

and this would affect the yield on the bonds. Investors who assumed that Congress would enact legislation to authorize repayment of Amtrak bonds were taking a risk. With federal backing, investors would consider Amtrak bonds to be about as good as Treasury bonds and would be willing to pay a premium for them.

Highway Aesthetics

Highways are traditionally and primarily built to be functional. They are an infrastructure that supports travel, is designed by engineers, and is concerned with matters such as network, navigability, and safety. At first sight, this utilitarian perspective leaves little room for any aesthetic sensitivity. However, the history of highway beautification in the United States dates back to the beginning of the 20th century.

In broad terms, highway beautification concerns the projects or actions for the conservation, enhancement, and/or stabilization of the roadside landscape. It is relevant for the study of transportation modes and infrastructures from the public policy point of view because it is intrinsically associated with issues of safety, of environmental and ecological sustainability, and of economic efficiency. It concerns not only short-range operations but also long-range planning.

Early Stages

In the first couple of decades of the 20th century, the first American parkways were constructed near the Bronx River in New York City as a greenbelt that would prevent pollution and erosion. All infrastructures surrounding these recreational roads had to comply with specific aesthetic standards. From then onward, and despite the proliferation of parkways for recreational use and commuter routes, issues concerning aesthetic sensitivity remained on the agenda, and in the 1930s some major road projects even incorporated landscape architects.

The American Association of State Highway and Transportation Officials (AASHTO) in 1930 adopted a resolution on roadside beautification. It addressed the conservation and enhancement of roadside plants, the beautification of town entrances, the creation of parks and rest areas, etc. In order to promote a more enjoyable use of roadways, it advocated the harmonious integration of landscape design, architecture, and engineering in the process of road planning.

However, during the 1940s and 1950s, the construction of roadways increasingly ignored the most basic environmental and aesthetic principles. The construction of the Dwight D. Eisenhower National System of Interstate and Defense Highways, also known as the Interstate Highway System, began in 1956, and the environmental and aesthetic disruption it originated became clear in the following decade.

Highway Beautification Act

The Bonus Act, adopted in 1958, was the first American legislation to encourage states to control outdoor advertising in the vicinity of the Interstate Highway System. It was a voluntary program that states could join, based on an agreement with the federal government in order to control outdoor advertising and thereby be eligible for a bonus payment.

The first major piece of national legislation with an environmental focus was the Highway Beautification Act. It followed President Lyndon B. Johnson's Great Society legislative agenda. The intention to beautify the country's highways was one of the first steps to improve the overall standards of quality of life in the United States. The Highway Beautification Act was adopted in 1965, against the backdrop of the "freeway revolts" of the 1960s, which focused on the potential negative impact of

highways in urban areas. At that time, public opinion emphasized the need to harmonize highways with their surrounding landscape, infrastructure, and historical sites.

The Highway Beautification Act called for control of outdoor advertising. This was to include the withdrawal of specific types of signs existing alongside the growing Interstate Highway System and the primary highway system. It also required the junkyards neighboring the interstate or primary highways to be either removed or screened. Finally, it clearly encouraged scenic enhancement and roadside development.

The act exempted direction and other official signs, on-premise and for sale or lease signs, and signs in zoned commercial and industrial areas. New signs to be erected were supposed to comply with specific size, spacing, height, and lighting criteria, and a just financial compensation was to be provided for the removal of previously legal billboards. In sum, a tremendous effort to harmonize

the image of the Interstate Highway System was being put in place.

However, the Highway Beautification Act has been no stranger to controversy. Some studies suggest that there are fewer billboards now than when it was enacted. Other studies suggest the opposite, considering the act to be a regulatory failure, because it has not succeeded in removing existing billboard clutter or preventing its spread. Some studies go so far as to state that during the past decades the Highway Beautification Act has all but been completely transformed into a sign industry-dominated program.

These studies claim that the act is in fact subsidizing the very industry it was meant to regulate by shielding it from the desire of state and local governments to implement effective control of the billboard issue. It is a fact that many legislative proposals to revoke or alter the act have been supported by the same environmental organizations that previously championed it, while the billboard industry

This stretch of Route 66 running through Missouri in 1953 was lined with billboards advertising commercial products and area businesses. The Highway Beautification Act, adopted in 1965, was the first major piece of national legislation with an environmental focus. Supported by growing public sentiment against highway advertising at the time, the intention was to beautify the country's highways as a first step toward improving overall quality of life in the United States.

has become one of its advocates. Besides its ineffectiveness in controlling the erection of new billboards along roadways, it has been used as validation for vegetation control, which in many cases is criticized for simply destroying vegetation located in the right-of-way in front of billboards.

Despite the fact that the primary objective of the Highway Beautification Act was to control the spread of billboards, a shift in public opinion revealed that a growing number of people considered billboards to be a good way to contribute to the safety and enjoyability of highways. While some still consider billboards to be ugly and intrusive, harming scenic beauty and bringing nothing of value, others perceive them to be interesting and potentially informative—useful to travelers. Billboards are also deemed to be able to create jobs and to help businesses attract customers. Studies conducted across the past four decades tend to confirm that the American public favors billboards, considering that their benefits outweigh any potential costs. Moreover, the support for a ban on billboards has been decreasing since the 1990s.

Twenty-First Century Challenges

At the turn of the century the issue of roadway aesthetics was firmly back on the agenda, as illustrated by the Transportation Equity Act for the 21st Century of 1998. The latter followed a decade-long process that began with the Intermodal Surface Transportation Act and the National Scenic Byways program, both of 1991. These aimed to protect and beautify both highways and roadways that were noted for their scenic, natural, historic, cultural, archaeological, or recreational quality. The concept of roadway aesthetics had now broadened to encompass both the Interstate Highway System and the network of less-traveled roads.

The concept of highway aesthetics not only returned to the policy agenda but also widened in scope, becoming much more than the plain control of outdoor advertising and other forms of visual pollution. For example, the Safe, Accountable, Flexible, Efficient Transportation Equity Act of 2005 was intended, among other things, to protect and enhance the environment, promote energy conservation, improve the quality of life, and promote consistency among transportation improvements and state and local planned growth and economic development patterns.

Alongside basic programs focused simply on the regular picking up of litter on roadsides, there can now be found new integrated functional policies that tend to focus on three groups of objectives: environmental sustainability, economic impact, and safety.

Environmental sustainability. There are programs implemented throughout the United States that aim to protect and enhance the natural roadside growth and forestry through focus on tree care and planting, land management, and soil and water quality. Roadside landscape projects can also become proactive tools to help manage stormwater, filter air, abate noise, conserve energy, and provide wildlife habitat.

Economic impact. Economic dividends may result from making a city or region a more attractive place to visitors and businesses. This can be achieved through techniques that create visual impact and a distinctive sense of place. The overall goal is to create a specific first impression and a lasting one. Roadside landscape is central to highway travel experiences, which in turn play a significant role in the perceived attractiveness of the places where people live, work, and visit. In this sense, highway beautification can be a profitable investment with positive returns.

Additional economic dividends may result from integrating different functions, besides transportation, throughout the network of highways. A series of facilities, such as sightseeing platforms, parking lots, toll plazas, traffic administration facilities, etc., may have a significant role to play in local tourism strategies, and in the direct or indirect creation of employment.

Safety. Some studies have suggested that beautified or scenic highways are also safer highways. The causal relation between highway aesthetics and safety derives from the fact that many elements used in beautification programs simultaneously contribute to safer traveling, for example, better lighting, less litter, controlled vegetation, places to stop and rest, etc. In addition, one tends to drive slower when the highway experience is more enjoyable.

This new integrated policy approach requires added care in terms of the planning, design, construction, and management of highway beautification programs. Three key issues stand out:

Context sensitive design. Highway beautification programs should be context sensitive. In other words, they should be site specific and take into consideration the communities and places where they are implemented.

Integrated approach. The Transportation Equity Act for the 21st Century called for an integrated approach to highway planning and design process that should include not only civil engineers but also architects, landscape architects, and urban designers. Highway beautification programs should build on multidisciplinary teams, interagency collaboration and public-private partnerships. They should be planned and designed in cooperation with other programs, such as those regarding drainage and maintenance, accessibility and transit, pedestrian and cyclist routes, safety, etc. A fundamental measure is to develop a monitoring and evaluation system to help track the costs of the programs, and their accomplishments.

Beautification as a long-term strategy. Those who defend the benefits of highway beautification programs agree that highway aesthetics should be a factor not only in short-range management operations but also in long-range public policy and planning.

In other words, in order to achieve its full potential highway beautification should be integrated not only into road maintenance procedures but also into the public policy processes of planning, design, and construction of roadways.

Highway and Road Safety

Highways and roads are one of the major factors in loss of life and serious injuries globally. According to the World Health Organization (WHO), approximately 1.3 million people die each year on the world's roads, and between 20 and 50 million more sustain nonfatal injuries. Road safety is a very difficult problem to address. While education and engineering may improve road safety in the long term, successful campaigns and effective enforcement may lead to quicker reductions in injuries and fatalities.

A basic concept in road safety is that the number of fatalities is a function of the road risk and the level of exposure of road users (to this risk). This implies that in order to reduce the level of fatalities, one needs to attempt to reduce the risk of traveling. Furthermore, when the exposure of the population to this risk is limited, then the overall number of fatalities is reduced.

The WHO Global Status Report on Road Safety 2013 provides an excellent overview of the current state of affairs in road safety globally. Road crashes are considered by the WHO to be a global health epidemic, and they are the leading cause of death for young people (aged 15 to 29). If current trends persist, by 2030 road traffic accidents will be the fifth-leading cause of death. While a significant number of countries (88, with a population of 1.6 billion people) managed to reduce road crash fatalities between 2007 and 2010, 87 other countries experienced increases of road traffic crashes during the same period. As expected, the higher road traffic fatality rates are found in middle-income countries, particularly the African region, where there is increasing motorization but poor road infrastructure, vehicle condition, and traffic education.

In the United States, over 34,000 people were killed in traffic crashes in 2012, a small increase over the low numbers in 2009–11, but a significant

reduction from the peak fatalities that exceeded 51,000 per year in the late 1970s. In 2011, approximately 30,100 people were killed in the European Union of 27 countries (EU27) as a consequence of road crashes. During the period from 2002 to 2011 in Europe, road fatalities decreased by almost 44 percent. Nine European countries achieved a reduction of more than 50 percent in the period 2001–11.

Traffic crashes are associated with a wide range of negative impacts, ranging from direct to indirect. The actions that can be used to reduce the number and severity (and therefore impact) of road crashes are often associated with economic costs. In order to evaluate whether a countermeasure should be used—or alternatively, which specific countermeasure to use—one needs to perform a cost–benefit analysis. In order to be able to do that, both “sides of the equation” need to be expressed in the same unit, usually monetary units. One of the parts of this equation that is most difficult to convert to monetary values is traffic fatalities.

Vulnerable Road Users

The drop in fatalities of motorized vehicle occupants in the more advanced (from a road safety point of view) countries in the world has turned attention to some of the more vulnerable groups of road users. In terms of mode of transport, vulnerable road users include pedestrians, bicyclists, and power-two-wheeler (PTW) riders; in terms of age groups, children and older travelers are particularly of interest.

Pedestrians are among the most vulnerable road users, accounting for 22 percent of all traffic fatalities, and the largest share of these are 65 years old or older. The WHO is calling on governments to take concrete actions to improve the safety of pedestrians. Children are particularly vulnerable. Each year, more than 800 children under the age of 15 are killed on European roads and 100,000 are injured.

According to the National Highway Traffic Safety Administration (NHTSA), in the United States, for example, despite the continuous decline in automobile fatalities, motorcycle deaths have increased every year between 1998 and 2011 (except in 2009 when there was a 16 percent decline). In 2011 4,612 motorcyclists died on U.S. roads, a 2 percent increase over those killed in 2010. Motorcyclist fatalities’ contribution is disproportionately high, as they are 14 percent of total highway fatalities, although motorcycle registrations are only 3

percent of total vehicle registrations. Safety analyses suggest that on a per-vehicle-kilometer basis, motorcyclists are 30 times more likely to die in a crash than car occupants, and five times more likely to be injured.

Addressing Road Safety

Road safety is a very difficult problem to address, as it incorporates a diverse group of factors and stakeholders that need to cooperate. While education and engineering may improve road safety in the long term, successful campaigns and effective enforcement may lead to quicker reductions in injuries and fatalities.

The risk of road travel can be reduced by infrastructure improvements, paying special attention to vulnerable road users, mitigation of distraction, and increased enforcement. Reduction of exposure can be the result of policies and also a result of exogenous factors, such as a recession, which restricts the ability of people to travel by car, or unemployment, which reduces the need to travel.

The assessment and improvement of road safety requires a large effort of data collection and analysis. A number of national and international organizations collect and aggregate road safety data, either at a global level, such as the Organisation for Economic Co-operation and Development (OECD) International Transport Forum (ITF) International Road Traffic and Accident Database (IRTAD), or at a regional or national level, such as the European Road Safety Observatory (ERSO).

The task of harmonizing road safety data into a larger database becomes particularly complicated because of differences in the way that data are collected and organized at each individual region. Even for seemingly simple concepts, such as that of a road crash fatality, different definitions (for example, counting those who die within 24 hours from the occurrence of the crash versus counting those who die within 30 days from the crash, which is the recommended approach) result in data that may not be directly comparable across regions. Common definitions are being developed and applied gradually, but they require change of procedures, which sometimes is very hard to implement in the field.

A related issue is that of underreporting, that is, the number of fatalities recorded by hospitals is consistently higher than that provided by the police (police are the source of traffic fatality data in the

majority—71 percent—of countries). It is more difficult for police to follow up on the outcome of traffic crash victims, suggesting that when data come from the police, underreporting tends to be higher than when data come from the health sector. While there are approaches to correct for this issue, the problem of incomplete data affects the quality of road safety monitoring programs.

Infrastructure Improvements

Inadequate and poorly maintained road infrastructure is often a contributory factor to traffic crashes. The severity of incidents may also be higher due to inappropriate road environment. For example, in a road without appropriate safety barriers or median, accidents may result in more severe injuries. Road safety audits and road safety inspections provide an important instrument in improving the safety of roads, both during the design and construction phases and during operation. These activities are undertaken by experienced, certified road safety engineers who identify limitations in the design or maintenance of the road so that they can be fixed in time.

Self-explaining roads and forgiving road infrastructure are two modern highway design concepts that aim to considerably improve road safety from an infrastructure point of view. The concept of self-explaining roads suggests that the roadway design should communicate to the drivers the appropriate driving patterns (for example, speed, headway, level of awareness) without the need for explicit signing. Therefore, the driver will be able to instinctively adopt an appropriate driving behavior for each roadway, thus limiting inappropriate driving conditions that could result in traffic crashes.

The concept of forgiving roads suggests that even when an accident does occur, the road design should provide the necessary safety elements (for example, safety barriers and median) to minimize the impact to the involved vehicles, drivers, and passengers and to the traffic (thus minimizing the danger for secondary incidents, which are often even more severe than primary incidents).

Monitoring and assessment of road condition is a very difficult task that is, however, essential to maintaining a safe road network. Not unlike the star ratings that are assigned to vehicles based on crash tests by EuroNCAP in Europe or NHTSA in the United States, organizations such as the

International Road Assessment Programme (iRAP), EuroRAP, and others offer road assessment programs. These programs inspect high-risk roads and develop Star Ratings and Safer Roads Investment Plans; provide training, technology, and support to authorities and road managers; and track road safety performance.

Distraction

Distraction has received considerable attention over the last few years as a leading cause of traffic crashes. The emergence of in-vehicle devices (for example, entertainment centers, in-dash navigation devices), as well as nomadic devices (for example, smartphones, tablets, personal navigation devices) offer an increasing amount of distracting visual and acoustic stimuli to the drivers. Furthermore, digital billboards and signs with pulsing, vivid lights contribute to a distracting road environment, potentially confusing the driver. Considering that the reaction window available to the driver in case of emergency is very small, it is evident that all these distractions can diminish the driver's ability to respond effectively to a dangerous situation and avoid the crash.

Vehicle, system, and device manufacturers and integrators are proposing alternative user interfaces that limit the need for drivers to take their eyes off the road; however, it is important to also consider the cognitive burden on drivers by responding to messages or queries by the systems.

There are three basic types of distraction: visual, cognitive, and manual. Often, a driver is distracted by a combination of these. However, distraction is not only related to technology or driving-related tasks. Talking with passengers in the car, smoking, or eating are also significant distractions. Most such distractions can be easily avoided by better organization and planning of activities by the driver.

Financial Conditions and Road Safety

Financial crisis and recession can lead to reductions in exposure to traffic risk due to a number of phenomena. (During the 2008 recession, the United States reached record low road crash fatality numbers, which were comparable to those in the 1960s.) Increased fuel prices, decrease of recreation mobility, and less heavy-goods vehicle traffic are some of the reasons that contribute to this temporary reduction in exposure. Higher

unemployment may lead to less need for travel and a reduction of risky driving.

As young people are usually most seriously hit by unemployment, this means that the more dangerous segment of the population (due to not only lack of experience, but also attitudinal and behavioral characteristics) do not travel as much, as fewer of them may afford vehicle ownership and travel. Finally, travelers may consider switching from car to public transport, which is, in general, safer.

While these factors are expected to have a positive effect on road safety, there are a number of competing factors. For example, dire financial situations may force travelers to shift modes from (less affordable) private car to walking, bicycles, and motorcycles. These latter modes, however, have a considerably higher risk associated with them. Furthermore, lower maintenance of vehicles may lead to some breakdowns or accidents, while poor road conditions may contribute to some crashes as well. The behavior of the drivers may also become more erratic, as they might transfer their financial problems to the road.

It is important to consider these effects when evaluating overall road safety levels, because such reductions that are not related to inherent road safety improvements will be countered once financial conditions improve and most people switch back to using the automobile more.

Traffic Law Enforcement

Traffic violations are a significant contributing factor to traffic crashes and fatalities. Enforcement is a means to prevent collisions from happening by way of persuading drivers to comply with the safety rules. Deterrence is based on giving drivers the feeling that they run too high a risk of being caught when breaking the rules.

The introduction of laws and regulations related to road safety has resulted in significant improvements in the level of road safety over time. Such examples include the introduction of seat belt, airbag, and ABS laws. Driving-under-the-influence control laws have also been implemented widely. For example, 111 countries (covering almost 70 percent of the global population) have comprehensive seat belt laws applicable to all vehicle occupants. Seat belts reduce the risk of a fatal injury by up to 50 percent for front seat occupants and up to 75 percent for rear seat occupants.

Enforcement is, of course, equally important, as laws may become inactive if accompanying effective enforcement strategies are not implemented. Traditional methods of police enforcement include roadside checks and the use of automated devices such as speed cameras. However, there are also technology-based approaches, such as alco-locks (in which a driver needs to breath into a breathalyzer before the vehicle may be started). Unlike infrastructure improvements, enforcement is a very cost-effective approach to improve road safety. Furthermore, traffic law enforcement is a measure that is usually supported by the general public.

Road Safety Initiatives and Campaigns

The increasing interest in road safety is being demonstrated by a large number of initiatives and campaigns aimed at improving road safety at a local, national, or international level. As motorization levels in less-developed (from a road safety point of view) countries increase, so are road crash fatalities expected to rise. The experience gained from countries that have applied successful strategies to improve their road safety level can be used to proactively improve the level of road safety in emerging countries and regions, thus saving large numbers of lives.

In 2010 the United Nations General Assembly unanimously adopted a resolution calling for a Decade of Action for Road Safety 2011–20, and for further Global Status Reports on road safety to monitor the impact of the program at national and global levels. The European Commission adopted a new target to halve road deaths by 2020 and, in its Transport White Paper in 2011, a “Vision Zero” for 2050. In order to achieve the 2020 target, the EU will have to surpass current reduction trends. To improve road safety, mass media campaigns have been widely used for decades. There is evidence that road safety campaigns can be effective, both for the general driver population and for special segments, such as professional drivers. One question that often arises is the degree of subtlety (or directness) that the campaigns should utilize in order to be effective.

Many policies and campaigns have been devised to sensitize people to road safety, aimed at shifting their perception and bringing this problem in the forefront of their consciousness. However, there are still vocal reactions that claim that shocking and scaring the public may not bring the desired results.

Besides the general public, road safety campaigns may be targeted at specific portions of the population, including professional drivers. Campaigns restricting the maximum time at the wheel for professional drivers, as well as laws prohibiting the transport of certain dangerous goods by road, include examples of such targeted campaigns.

Modeling Road Safety

Modeling road safety is a complex task that needs to consider both the quantifiable impact of specific parameters and the underlying trends that cannot always be measured or observed. The sensitivity of users to road safety campaigns, the improved quality of the vehicle fleet, the improvement of the driving skills of the general population, and the overall improvement of the condition of the road network are only some of the aspects that cannot be easily modeled directly. Therefore, modeling should consider both measurable parameters and the dimension of time, which embodies all remaining parameters.

Macroscopic modeling can provide insight into this problem and support policy makers in developing countries to adjust their policies in reaction to the changing macroscopic conditions.

For example, developing insight (regarding the expected breakpoints in road safety fatality trends, as identified from the developed countries time series) can be applied to performing more accurate future predictions for developing countries (which have still not reached the motorization levels of developed countries). Macroscopic, in this context, implies the analysis of aggregate (monthly or annual) accident and fatality data rather than the more detailed and disaggregate (in-depth) analysis of individual accidents. In-depth data can also provide very valuable insight about accident causation and contributing factors.

Although significant steps have been taken to improve road safety during the past decades (at least in the more developed countries, in terms of road safety), there are still several significant challenges that need to be addressed. Road safety statistics have traditionally focused on fatalities. While this is clearly a big part of the problem, serious injuries are also very important, as they often result in temporary or permanent disability.

Highway Construction and Maintenance

Modern road and highway construction in the United States follows a standard set of procedures for the entire process. Road construction design is the initial part of the process. A good design balances cost, safety, mobility, and social and environmental impacts. To achieve this balance, highway

designers use criteria that have been established through years of testing and research in the fields of highway engineering (including materials testing), traffic operations, and safety. Roadways and highways in the United States must comply with federal guidelines, even on state and local levels of construction. The U.S. Federal Highway Administration (FHWA) has adopted design standards for roadway geometrics, bridges and structures, erosion and sediment control, hydraulics, traffic noise, materials, and accessible pedestrian design. These standards apply to all projects involving the National Highway System (NHS). Design standards also apply to road maintenance, such as resurfacing, restoration, and rehabilitation (3R) projects.

The Process: Planning

The plan for the construction of a road or highway varies from one job to another and depends on (among other criteria) available financing, foundation and topography (environmental) conditions, nature of available materials and construction equipment, and the forecast for the type and volume of traffic for this particular roadway. Any road construction job consists of a number of basic steps, although, depending on the job, the relevant importance and the interaction among these steps will vary. These steps can be summarized as planning, programming, and preconstruction activities; site clearance; surveying and setting out; earthworks; bridge construction (if this applies); drainage structures; pavement construction; placement of road surfacing; placement of road furniture; and, landscaping.

A particular “document” read by many highway planners and engineers that is widely circulated and known as the basics of proper road planning is called “The Ten Commandments of a Good Road.” (The origin of this popular paper is a pamphlet printed at St. Michael’s College in Vermont in 1984.) It contains sage advice that is still passed around to those in the field of roadway or highway construction.

According to this paper, “The Ten Commandments of a Good Road” are the following: (1) get water away from the road, (2) build on a firm foundation, (3) use the best materials available, (4) compact all materials well, (5) design for winter maintenance, (6) build for traffic loads and volumes, (7) pave roads only when they are ready, (8) build from the

bottom up, (9) protect your investment, and (10) keep good records.

Preconstruction Activities

Before any building or construction can begin, a host of preparatory activities must take place at the construction site. These include surveying, setting out of stakes, site clearing, and site layout. Site-based management can significantly improve cost and time savings during the construction process without requiring much additional work. Site management involves many tasks, including site investigation before the construction process begins, material procurement and delivery, systematic performance monitoring, information collection, maintenance of site records, and communication among various responsible parties involved. Construction site layout involves identifying, sizing, and placing temporary facilities within the boundaries of the construction site. These may range from simple lay-down areas to warehouses, fabrication shops, maintenance shops, and residence facilities.

Earthwork

Earthwork is one of the major components of road construction. It is also one of the most important, as it literally lays the foundation for the road. Without adequate support, a road will deteriorate rapidly. A good road requires a suitable foundation composed of stable material, because the road base determines the service life of a road. The earthwork process includes excavation, material removal, filling, compaction, and construction. Moisture content must be controlled, and compaction is done according to standard design procedures. The eventual aim of the earthworks phase of construction is to position the subgrade underlying the pavement layers in the right location and at the correct level, and to provide drainage.

Some of the operations involve creating cuttings by excavating through high ground, formation of embankments by filling over low ground, shaping the finished surface to design levels, and excavating for drainage systems. A typical sequence of operations is the cut, which is excavation to the depth necessary to reach the formation level; transportation of any undesirable materials away from the site; suitable disposition of any excess cut material; and hauling suitable materials from cuts to fill areas. Next in the sequence is the fill, which

is drainage of water from depressions and disposal of any unsuitable underlying material; spreading of fill material in horizontal layers to the required thickness (usually not more than 250 millimeters); and thorough compaction of these layers to required the density.

In the process of filling a depression to reach the road level, the original bed is flattened after the removal of the topsoil. The fill layer is distributed and compacted to the design specifications. This procedure is repeated until the desired compaction is attained. The fill material should not contain organic elements, and should possess a low index of plasticity. Fill material can include gravel and decomposed rocks of a particular size but should not contain huge lumps of clay. Sand clay can be used. The area is considered to be adequately compacted when the roller movement does not create a noticeable deformation.

Drainage Structures

The importance of drainage cannot be overemphasized in road construction and maintenance.

Construction workers lay down a 4-inch warm mixed asphalt base layer before adding a top layer of material during a Federal Highway Administration project in Texas in 2011.

Storm drainage and ecological concerns must be considered seriously. Sediments and erosion need to be controlled to avoid damaging effects. Drainage systems must be constructed so that they are able to carry storm- and wastewater to a waterway, stream, or river, and eventually to the sea. Water affects the entire serviceability of a road. Too much water in the base and subgrade materials weakens the road. Water allowed to remain on top of a road weakens the surface and causes potholes and cracking. Water can saturate the base, erode slopes and ditches, ruin road surface and shoulders, and, during the freeze–thaw cycle, destroy the entire road structure.

A well-engineered surface drainage design is the best way to lessen water damage on a road and to lessen future maintenance costs. Proper surface drainage prevents water from infiltrating the pavement surface and removes water from the driving lanes to side ditches, which carry the water away from the road. A surface drainage system has four main components:

- **Road crown:** The road crown allows surface water to run into the side ditches.
- **Shoulders:** Shoulders are an extension of the road surface and allow for the passage of surface water to the ditches.
- **Ditches:** Ditches are used to carry water away from the roadway. Water collected and carried to the ditch has to be directed away from the roadway at frequent intervals, sometimes using a culvert.
- **Culverts:** Culverts usually channel water from one side of the road to the other, helping control the flow of water and slowing it down to reduce erosion.

Pavement

Three main types of pavement are used in roadway and highway construction: gravel and crushed rock pavement, asphalt pavement, and Portland cement concrete pavement (PCC). PCC is the most commonly used road material in the United States. For highways, the general pavement construction procedure involves placement, consolidation, finishing, curing, and jointing in rapid succession.

Placement involves any equipment or procedures used to place the delivered PCC on the desired surface at the desired thickness. During the screeding

(or strikeoff) process, excess portions of the roughly placed PCC are cut off in order to bring the slab to the required elevation. This is usually done by dragging a straightedge across the slab at the required elevation. Consolidation involves any means used to eliminate undesirable voids. This is typically accomplished with the use of vibrating machines.

Finishing involves any equipment or procedures used to impart desirable surface characteristics. Generally, finishing can be divided into floating and texturing. Curing is the maintenance of satisfactory moisture and temperature in PCC as it sets and hardens such that the desired properties can develop, and jointing involves all those actions used to insert purposeful discontinuities in the pavement and to seal them appropriately.

For most of the 20th century, the same materials—Portland cement, high-quality aggregate, and water—were used in pavement concrete, with only minor changes. In the past two decades, the industry has experienced more changes than those that occurred in the previous 80 years due to changes in road use, availability of materials, environmental issues, policy, and financing. In order to meet these growing demands on highway construction and rehabilitation, several joint projects between cement companies and the FHWA have been researching new materials and processes for highway pavement construction.

Road Surfacing

The surface course is the layer in contact with traffic loads and normally contains the highest quality materials. It provides characteristics such as friction, smoothness, noise control, rut and shoving resistance, and drainage. In addition, it serves to prevent the entrance of excessive quantities of surface water into the underlying base, subbase and subgrade. Road surfacing materials may be gravel, sprayed bituminous seal, asphalt, or cement concrete.

This top structural layer of material is sometimes subdivided into two layers, the wearing course and the intermediate/binder course. The wearing course is the layer in direct contact with traffic loads. It is meant to take the brunt of traffic wear and can be removed and replaced as it becomes worn. The intermediate/binder course is the layer that provides the bulk of the hot mixed asphalt (HMA) structure. Its chief purpose is to distribute load.

Road Furniture

“Road furniture” is the term used in reference to pieces of equipment installed either after a road or highway is complete or toward the completion of construction. These items include structures such as light signals, traffic signs, street lights, fire hydrants, transit stops, and community amenities such as benches, waste containers, water fountains, and restrooms. Some roadways and highways are designed to incorporate memorials or local artwork such as sculpture and murals. Road furniture is not just an afterthought. The ideas should be in place in the initial planning phase; in fact, some of these components are integral and necessary parts of the entire infrastructure.

Landscaping

Landscaping is considered a major element in highway design, as its effects are far reaching. Four components that for decades have been a part of what is referred to as “the complete highway” are utility, safety, beauty, and economy. These ideals are intertwined and may all be realized through landscape planning and design. Among many benefits to a roadway, landscaping helps enhance the mobility of people and goods, encourages economic prosperity, and preserves the quality of the environment and communities. It is a major consideration in smart growth planning and development policies.

Highway Preservation and Maintenance

The American Association of State Highway and Transportation Officials (AASHTO) defines preventive maintenance as “the planned strategy of cost effective treatments to an existing roadway system and its appurtenances that preserves the system, retards future deterioration, and maintains or improves the functional condition of the system without increasing structural capacity.” Preventive maintenance activities are those that address aging, oxidation, surface deterioration, and normal wear and tear from day-to-day performance and environmental conditions. Preventive maintenance activities extend the service life of the roadway asset or facility in a cost-effective manner.

Timely preventive maintenance and preservation activities are necessary to ensure proper performance of the transportation infrastructure. A 1997 report to Congress titled “Status of the Nation’s Surface Transportation System: Condition and Performance” warned that more than 48 percent of the

nation's rural interstate highways and nearly 60 percent of urban interstate highways have pavements rated fair to poor. From these numbers, it is evident that the condition of the U.S. highway infrastructure has been deteriorating. Yet the demands on the U.S. transportation infrastructure are greater than ever.

Increasingly, state departments of transportation (DOTs) report that the proactive approach of preventive maintenance—instead of the typical strategy of fixing the worst first—cuts the need for costly, time-consuming reconstruction and rehabilitation projects while reducing associated traffic disruptions. Experience has shown that when properly applied, preventive maintenance is a cost-effective way of extending the service life of highway facilities. By using lower cost system preservation methods, local and state governments can improve system conditions, minimize road construction impacts on the traveling public, and better manage their resources needed for long-term improvements such as reconstruction or expansion.

Typically, regional offices work proactively with their State partners to establish a preservation component of planning, which is composed of various preventive maintenance activities and treatments. These include roadway projects such as joint repair, seal coats, pavement patching, thin overlays, shoulder repair, restoration of drainage systems, and bridge activities such as crack sealing, joint repair, seismic retrofit, scour countermeasures, and painting. Other activities that at one time were considered routine maintenance may now be considered as preventive maintenance (extending service life). These can include such work items as regional projects for periodic sign face cleaning, cleaning of drainage facilities, corrosion protection, and spray-applied sealant for bridge parapets and piers.

Planning

State DOTs utilize maintenance management systems to collect data from surveys, inventories, and inspections, to prepare roadway conditions assessments, and to manage highway infrastructure assets, accordingly. Core assets that should be addressed are pavements, bridges, tunnels, stormwater systems, and appurtenant facilities. Additional assets that may be included are shoulder/sidewalks, slopes, rock-fall, slope protection, and vegetation.

Some state DOTs use a roadway characteristics inventory (RCI) to track their roadway assets to

plan for their maintenance and repair. Many DOTs conduct RCIs on an annual basis to update and maintain their data relative to these assets. These inventories typically include hundreds of infrastructure features or characteristics organized into various categories, for example, types of guardrails or fencing. The inventory will take into account the amount (or mileage) of an asset, rate the existing quality of parts of the structure, and determine the level of maintenance required.

One of the more challenging aspects of designing a conditions assessment is selecting the performance characteristics or criteria that will be used to rate each asset. For example, guardrail repairs are performed to keep the guardrails functioning as intended. Therefore, the percent of guardrails that are functioning as intended might be used as a performance criteria. Another example would be culverts, using the attributes of clogged flow, interrupted flow, and structural deterioration.

More recently, there has been a push to integrate the concept of sustainable highway systems that take into account environmental, economic, and social equity dimensions in addition to fulfilling the functional needs of transportation. Preventative maintenance must take into account recycling and reuse of materials, vegetation management, and environmental impacts, among other components, while developing asset management. For sustainability to be fully integrated into highway programs, it must be considered throughout the project lifecycle, from planning through operations and maintenance.

Highway Design and Engineering

The art and science of highway design and engineering has been constantly evolving since ancient times. Notably, the Roman Empire connected and policed its sprawling provinces and colonies by means of well-constructed roads, causeways, bridges, and viaducts—many of which have lasted millennia and are still in everyday use by today's wheeled vehicles. These thoroughfares might not have lasted so long had it not been for the salient fact that the hands-on, materials-science knowledge of those Roman builders and craftsmen was matched by the administrative energy and expertise of the specifiers, engineers, and designers. Every mile of every road had to be surveyed and laid out in a certain way and then built and maintained under a very specific regimen.

In the modern era, the designers and engineers of highway networks may be excused for sometimes thinking that there are more "bureaucrats" than warranted. Even though the highway systems of the world carry billions of passengers and vast tonnage of goods to all but the most remote areas of the inhabited world, it may seem that no stretch of road is beyond the reach of lawmakers

and policy administrators with a burning desire to tweak, amend, update, change, and challenge the existing ways and means of highway construction.

Yet there are very sound reasons—practical, moral, social, and professional—for this state of affairs. The dramatic results in the decline of traffic fatalities is one of the more obvious justifications for maintaining comprehensive and up-to-date codes and enforcement of highway layout and building methods, and an inducement for authorities to continue funding improvements quite generously within policy guidelines. In the United States, for example, according to data compiled by the National Highway Traffic Safety Administration (NHTSA), the number of fatalities per 100 million vehicle miles traveled (VMT) was cut from 5.06 fatalities/VMT in 1960 to 1.11 in 2010. Components of this drop included: better driver education, better automotive safety technology, more aggressive enforcement of anti-driving-while-impaired (specifically targeting alcohol) laws, and improved highway design and construction practices.

Strategic Plans and Funding

In seeking advanced solutions for improved roadway design, highway engineers can call upon a diverse and sophisticated body of research and design recommendations. They also can partner with transportation authorities in various jurisdictions to develop plans to avail themselves of funding sources specifically earmarked for these adaptive highway design options. As one example, the Transportation Research Board (TRB), an institutional component of the National Academies, joined with the American Association of State Highway and Transportation Officials (AASHTO) standing committee on highway traffic safety as well as the Federal Highway Administration and the NHTSA in a 1997 initiative to study ways and means of improving safety on American highways. Among the 22 focus areas identified were several that addressed roadway infrastructure design and engineering. The study led to pooled funding that was administered under the new AASHTO Strategic Highway Safety Plan.

This plan has been updated periodically with fresh research results, recommendations, and funding availability for implementation. For example, in 2003 the National Cooperative Highway Research Program (NCHRP) issued an exhaustive report on unsignalized intersection accidents that included

highway architectural and engineering concepts shown by evidence to prevent such accidents and significantly reduce the severity of those accidents that still might occur. Among the ideals were traffic calming, improved management of access near such intersections by means of roadway architecture and geometric design improvements, adaptations to yield better sight distance, and installation of such supportive features as splitter islands, stop bars, rumble strips, warning signs, flashing beacons, and improved maintenance of signs and other features.

The report enumerated a range of expected costs—covering material, equipment, and personnel—for everything from restriping pavement areas to road-widening projects. Public information and awareness programs were emphasized as an ancillary cost driver, but one that would yield higher benefit return, especially when reengineering projects first come on line. Administrative costs, too, were considered, as changes of policy, design guidelines, and criteria are seen as core attributes of a functioning mitigation program.

The report also pointed to a range of potential funding sources, from private-property owners to specific local, state, and federal highway agencies. AASHTO and NCHRP emphasized that priorities and goals vary widely from state to state, and it is under these priorities and policies that highway designers and engineers must operate. It is also within the understanding of this context that engineers should team with their policy-making and administrative authorities when preparing funding requests. For example, the agencies pointed to the variance in traffic incident reduction goals of several states within the same general time frame of 2002–05. The goals varied not only quantitatively but by qualitative measure as well. Pennsylvania sought to cut fatalities by 10 percent, while California adopted a 40 percent fatality reduction goal, as well as a 15 percent cut in injury-causing collisions and a 10 percent cut in work zone crashes.

Among the more extensive, state-based highway design resources is that administered by California, through its Caltrans department. With rules covering everything from computer-aided design standards to storm water collection and dissipation engineering methods, and with a served population exceeding 30 million, Caltrans regularly issues Design Information Bulletins that address such topics as freeway interchange safety improvements; public

boat launch access ramps; culvert repair practices; material disposal, staging, and borrow siting; and capital preventive maintenance guidelines. Each of these subject areas anticipates and incorporates public hearing processes and policies.

Layout Fundamentals

Much of highway design stems directly from safety concerns, and the predominant factor in much of the inherent safety level of any segment of roadway derives from issues of visibility. Allowing for specified traffic volume, access, and speed requirements, designers must integrate carefully calibrated line of sight, sight distance, lane alignment, and accommodation of anticipated nonroadway visual elements, such as the natural setting and the built environment. There are also standards for roadway cross-section, clearances, grade, alignment, lane width, curve radius, acceleration and deceleration areas, and shoulder width. With the expansion of bicycle traffic beyond urban areas to highways, especially at choke points such as bridges and overpasses, the incorporation of safe bicycle and pedestrian lanes and barriers are an additional area of engineering and rulemaking.

A variety of solutions can be offered for material specifications, with the most fundamental decision being whether the road will be surfaced with a pavement derived from asphalt or from concrete. Another fundamental is the choice of rigid or flexible pavement, each of which has advantages and drawbacks in terms of service life, pavement fatigue and distress, friction quotient, vulnerability to development of roughness, and permeability. The layout starts with surveying—but it does not end at the side of the road. Today more than ever, legal requirements to protect and support specified levels of environmental integrity and human community quality of life mean that designers must generate plans to satisfy policy standards by local and state jurisdictions for noise abatement, visual wholeness, community cultural significance, water runoff, erosion control and stormwater overflow mitigation, and related criteria.

Driver Behavior Factors

Many fundamentals of highway engineering have a design basis that may touch upon more complex interactions than at first appear possible. The importance of the highway shoulder is one such apparently straightforward element that actually

can influence a host of seemingly nonrelated factors, especially driver behavior.

A road shoulder is often referred to as a “break-down lane.” That is one designed-in function: to provide a relatively safer area for motorists in distress to pull off the main traffic lanes until assistance can arrive or quick repair can be accomplished. However, the shoulder of a highway also provides a deeper psychological effect that can exert very real and very powerful physical forces on individual drivers and on traffic flow. It has been documented that on roadways that lack shoulders but do have instead a guardrail, wall, precipice, or other limiting physical barrier along the road boundary, many drivers tend to “cheat” their vehicles away from the outer boundary of the road, thus crowding toward the adjacent lane, whether traffic in that lane is moving with or against their own direction. This tendency, in turn, will in most cases cause prudent drivers to reduce speed—not necessarily the intent of the highway designer—and lead to greater congestion.

However, a large portion of drivers of a less steady nature may tend to weave between outer and inner lane boundaries; they may overreact, oversteer, and begin to precipitate real danger of loss of control or even collision. Even if an accident does not develop from such a situation, the capacity of the shoulder-less segment of highway has been effectively reduced. Again, this was likely opposite to the intent of the highway designer, but it is a result of failing to take into account the psychology, expectations, perceptions, and behavior of the driving public.

Every measure must be directed toward designing the highway to present the driver with overt, clear, visual, and mental cues that will direct his or her actions and decisions and “reward correct decisions” by meeting expectations in layout to which the prudent driving public has grown accustomed.

Maintaining Policy Goals

Highway design, surveying, construction, and maintenance practices impact many aspects of public policy in the sophisticated, highly interconnected world of today. In this context, the continually reviewed and improving policies and practices for proper highway engineering must meet local community, regional, and national criteria for public and private input as well as ever more challenging economic and environmental parameters. Budgetary factors of both the long-term capital investment

nature and the ongoing operational type underlie many decisions in highway engineering.

Due to this major fiduciary impact, and its municipal, state, and federal tax and revenue components, highway engineering will remain a core expense for the foreseeable future. It is also one that can only be properly approached and managed through cooperation and information sharing between the appropriate planning and operational agencies. By the same token, better coordination and improved policy-making practices can and do help deliver positive input to local and regional economies.

Highway Finance

Following passage of the Federal Aid Road Act of 1916, highways and roads became an intergovernmental responsibility. Though the federal government has played the dominant role in setting nationwide highway priorities, states and localities have been involved in implementing policies, including financing and ownership of the roads and highways. The funds for highway construction, operation, and maintenance come from all levels of government—from bond sales and the general fund, in part, but mostly from a variety of highway user charges, including fuel and other excise taxes, tolls, and other user fees.

As summarized in Table 1, states collect the most own-source revenues for highways and roads (\$109 billion, or 49.3 percent of all highway revenues in 2010), followed by the federal government (\$59 billion, or 26.7 percent), and local governments (\$53 billion, or 24 percent). While the bulk of the revenue used to finance roads and highways comes from federal and state fuel taxes, other sources include various fees and sales taxes on automobiles, as well as tolls and bond proceeds.

Highway User Charges

Highway user charges are fees imposed primarily on highway vehicles, motor fuels, drivers, and other elements associated with highway and road use. The most common forms of user charges are tolls and fuel taxes, which levy charges that are roughly proportioned to the use of the road. A highway or road toll is a direct user fee charged for utilizing a particular road or highway facility.

The revenue derived from the toll is often used to cover the debt service incurred to design and build the road, bridge, or tunnel facility; to maintain and operate the facility; and to provide the basis for subsequent bond issues to finance facility improvements and expansions. For most states, toll financing has been undertaken on a project-by-project basis, rather than as an integral part of the states' financing strategy. In 2011, the 5,541 miles of toll roads, bridges, and tunnels generated approximately \$8.2 billion and \$2.5 billion for states and localities, respectively.

The federal government and the states levy fuel taxes on gasoline, diesel, and other special fuels. These taxes are levied as a flat rate per gallon and are collected from the refiner, manufacturer, or importer of the fuel and passed through the retailer to the highway user. At the state level, the average tax rate (weighted according to volume) on gasoline and diesel are 21.382 cents per gallon (cpg) and 21.338 cpg, respectively. The federal tax rate on gasoline is 18.4 cpg, and on diesel it is 24.4 cpg.

These fuel taxes are a category of highway-related excise tax. Other excise taxes include taxes imposed on tires, vehicle sales, and on the use of heavy vehicles. The federal excise tax on truck tires is an example of a highway-related excise tax. The premise for this tax is that trucks, because of their weight, cause much greater damage to roads and bridges, and the excise tax on their tires serves as a proxy for highway wear-and-tear charges.

At the federal level, the excise tax applies to tires purchased for vehicles with load capacity in excess of 3,500 pounds. The tax structure is somewhat proportional to the load capacity but may not

Table 1 Total receipts for highways (in billions and percentage of total) by government level

Year	Federal Government	State Governments	Local Governments
1950	\$0.50 (10.8%)	\$2.84 (61.6%)	\$1.27 (27.5%)
1960	\$3.06 (26.6%)	\$6.06 (52.7%)	\$2.37 (20.6%)
1970	\$6.14 (28.2%)	\$11.74 (54.0%)	\$3.87 (17.8%)
1980	\$9.83 (24.7%)	\$19.67 (49.5%)	\$10.22 (25.7%)
1990	\$14.43 (19.2%)	\$40.03 (53.2%)	\$20.84 (27.7%)
2000	\$30.82 (23.5%)	\$66.43 (50.7%)	\$33.86 (25.8%)
2010	\$58.95 (26.7%)	\$108.96 (49.3%)	\$53.07 (24.0%)

Source: Federal Highway Administration. "Highway Statistics 2010." <http://www.fhwa.dot.gov/policyinformation/statistics/2010>

cover all the costs imposed by trucks. While most states impose a tax on motor vehicle sales, this tax is typically not considered highway-related revenue because receipts are directed to the General Fund and not dedicated for highway spending. However, in some states, the motor vehicle sales tax is dedicated for transportation purposes.

Other highway user fees include a variety of fees associated with licenses, permits, and registrations. Interstate motor carriers, for example, purchase licenses, decals, or permits associated with the International Fuel Tax Agreement (IFTA) to operate in an IFTA jurisdiction. Vehicle registration fees, another example of user fees, are levied by every state on passenger and commercial vehicles. These fees are assessed according to various vehicle characteristics or combinations thereof, including a flat fee, by weight, by age, and by value. In some states, local governments may also collect highway revenues from vehicle registration fees.

Federal Highway Finance

At the federal level, highway finance is dominated by the gasoline tax. The federal government also imposes taxes on gasohol and other special fuels, but these provide minimal revenues. The Highway Trust Fund (HTF), which is the dedicated source of highway funds at the federal level, includes receipts from these and truck-related excise taxes. In 2011 the HTF revenue came from the following sources: diesel and special fuels tax (25 percent); gasoline (64 percent); and truck-related (8 percent). The truck-related taxes include three categories that impose taxes on heavier vehicles and their tires.

The tires tax, for example, increases from no tax on tires for vehicles with rated load capacity under 3,500 pounds to a tax of 9.45 cents for each 10 pounds over 3,500 pounds. The truck and trailer sales tax is 12 percent of the retailer's sales price for tractors and trucks over 33,000 pounds gross vehicle weight (gvw) and trailers over 26,000 pounds gvw. The heavy vehicle weight tax is an annual tax

Table 2 Sources of state and local revenues for highways

	2010	2005	2000	1995	1990	1985	1980
STATE REVENUES							
State general fund appropriations	4.7%	2.8%	4.5%	2.3%	3.3%	2.5%	5.2%
Federal funds	25.6%	23.9%	26.1%	27.9%	30.8%	30.7%	38.4%
Bond proceeds	18.6%	17.6%	9.9%	6.8%	7.1%	13.4%	4.1%
Roads and crossing tolls	5.1%	5.3%	5.1%	5.1%	5.8%	5.2%	5.6%
Motor fuels tax	19.6%	32.0%	38.2%	46.1%	60.6%	52.1%	57.4%
LOCAL REVENUES							
General fund appropriations	27.5%	29.5%	30.1%	26.2%	32.0%	28.6%	30.1%
Federal funds	1.7%	2.1%	2.1%	1.7%	2.6%	5.6%	7.7%
State funds	29.7%	23.8%	26.2%	28.1%	28.2%	23.9%	24.7%
Bond proceeds	9.6%	10.6%	7.1%	13.2%	8.3%	14.3%	9.5%
Roads and crossing tolls	2.1%	2.2%	1.8%	1.1%	0.6%	1.1%	0.6%
Property taxes, special assessments	18.7%	20.1%	19.3%	16.2%	18.0%	16.3%	17.5%
Local highway-user revenues (Motor fuel and motor vehicle tax revenues)	3.1%	3.5%	3.8%	3.4%	2.9%	2.0%	1.3%

on trucks 55,000 pounds and over gvw—a tax of \$100 plus \$22 for each 1,000 pounds (or fraction thereof) in excess of 55,000 pounds (up to a maximum tax of \$550).

State and Local Highway Finance

User fees and bonds secured by highway user fees have been the predominant source of funds to finance highway improvements in most states since the early 1920s, but it was not until the Highway Revenue Act of 1956 (which created the HTF) that user charges (and the fuel tax, more specifically) became the major source of federal funds for highways. Local and state governments, through various mechanisms, receive fund transfers from the federal motor fuel taxes and other revenues, but they also pay for roads with other own-source revenues such as fuel taxes, road user fees, and general revenues.

Each state develops its own mix of fuel taxes and road user fees (often deposited into a dedicated Road Fund, which is equivalent to the federal Highway Trust Fund) and supplements it with federal funds, transfers of general revenues (not transportation related) from the General Fund, and other sources. In 2011, state gas taxes on gasoline varied from a low of 7.5 cpg in Georgia and 8 cpg in Alaska to a high of 37.5 cpg in Washington. The diesel tax similarly varied from 7.5 cpg in Georgia and 8 cpg in Alaska at the lower end to 46.2 cpg in Connecticut at the upper end.

Table 2 reveals the shifts in the sources of state funding for highways between 1980 and 2010. Federal funds dropped from 38.4 percent to 25.6 percent of total funding. Reliance on transfers from state General Funds have generally been less than 5 percent of revenues, while toll revenues have been fairly constant at just over 5 percent of total funding. Reliance on bonds has risen dramatically from 4.1 percent of revenues to 18.6 percent. The drop in the contributions of the fuel tax is precipitous—from 57.4 percent of total revenues in 1980 to 19.6 percent in 2010.

In contrast, a similar examination of sources of highway revenue for local governments exhibited a fairly stable trend over time. In 1980, appropriations from the General Fund composed 30.1 percent of total revenues for local governments. In 2010, this source composed 27.5 percent of total revenues. Local governments relied on 24.7

percent of their revenues from the state in 1980, compared to 29.7 percent in 2010. This increase in state funds compensated for the decline in federal funds from 7.7 percent in 1980 to 1.7 percent in 2010. Local highway-user revenues such as from the motor fuel tax and motor vehicle tax have consistently comprised less than 3 percent of total revenues. Bond proceeds were 9.5 percent and 9.6 percent of total revenues in 1980 and 2010, respectively.

Funding Shortfalls

The significant reliance at the federal and state levels on motor fuels tax revenues has resulted in highway funding shortfalls. One factor contributing to this shortage is well known—fuel tax revenues are declining as vehicles become more fuel efficient. According to data from the Bureau of Transportation Statistics, the average automobile fuel efficiency was 13.9 miles per gallon (mpg) in 1975, compared to 21.1 mpg and 22.6 mpg in 1995 and 2008, respectively.

In addition, states and localities now have a substantially larger highway/road system to maintain. Research by J.-E. Yusuf and L. O’Connell documents that lane miles of principal arterials have increased by more than a third between 1982 and 2007. When coupled with a large increase in construction costs and virtually no increase in the fuel tax rate (measured in real terms), this growth in mileage has resulted in lower revenues to finance construction, maintenance, and operations of highways and roads.

From 1982 to 2007, the Federal Highway Administration (FHWA) construction price index (adjusted for general inflation) rose 150.1 percent but the real gas tax rate (adjusted for general inflation) was almost identical in 1982 and 2007. Thus, the increase in vehicle fuel efficiency is but one of the problems confronting the states. They have more lane miles to maintain and the rise in construction cost has substantially outstripped the rise in fuel tax rates.

One obvious solution to addressing highway finance needs is to raise the motor fuels tax at the federal and state levels. Yet, in recent years few states have done so due to the lack of popularity of tax-raising measures. An alternative would be the adoption of a variable rate tax structure that would index the rate to some measure of inflation. This

would produce small but frequent (and more politically acceptable) rate adjustments.

Highway Interchange and Ramp Design

A highway interchange refers to the designed junction of two or more roads at different heights, or grade separation (essentially one road passes over another), that uses one or multiple ramps as a way to permit the freest possible flow of traffic involving the movement between roads. By maneuvering multiple lanes of traffic going in different directions, grade separation helps keep traffic flow at these crossroad sites moving efficiently and safely through a series of merges. Ideally, the highway interchange prevents traffic from at least one highway artery from having to directly cross any other traffic stream. Even if in an effort to help manage access traffic off the directional ramp or to maintain traffic flow on slip roads (short sections of roadways designed to move traffic to highways) traffic lights are installed, the traffic stream is only minimally

intruded. Highway interchanges are designed to handle capacity traffic and, in turn, to maximize the efficient movement of a massive volume of lane traffic at cross-purposes.

Because the interchange is such a routine part of highway navigation and surface transportation systems and because appreciating the design elements can require a familiarity with engineering design basics and a bird's-eye perspective above the roads themselves, drivers seldom appreciate the engineering that must go into the design of both interchanges and ramps. Nor do drivers recognize the sheer variety of conceptual models available to give transportation engineers a wide range of design options, as exchanges and ramp systems must account for conditions and variables including vehicular traffic flow and volume and type, topographical grades, the land-sprawl available for development, and even the weather (including wind and sun positions). Because vehicles must regularly (and safely) change not only direction but entire roadway systems, highway interchanges help create optimum transit conditions, although design features can create negative (and anxious) driving conditions, most notably manifested in lane jumping or weaving in which drivers must contest, often at high speeds, for access to appropriate turns. In general, however, interchanges make arterial traffic stream itself possible.

Most often highway interchanges connect freeways (controlled-access highways) or expressways (limited-access highways) with surface streets. Thus highway interchanges and ramps are ways to manage busy highways by allowing a full range of direction options to enter or exit in each direction. The design of highway interchanges and ramps is not only to maximize traffic flow but also to contain and direct it as well. For instance, heavy volume traffic trying to access highways can be controlled through the use of ramp meters, essentially street lights that modify access patterns to prevent clogging or accidents from careless access to busy highways.

Given the volume of vehicular traffic (in many urban areas more than 200,000 vehicles are accommodated on any single day) and the network of entangling roadways that now serve most metropolitan areas with over 50,000 populations, the design elements of highway interchanges must take into account the human factor in transportation systems. Confusion is easy

to generate—already heavy traffic can be quickly complicated when, to accommodate an approaching interchange, four lanes suddenly open to six or six suddenly opens to eight. In quick succession, a series of overhead signs, all the same size and color with no distinguishing or helpful indicators, give at best loose direction for quickly approaching exit ramps designated most often by mileage markers and giving options for interchange actions listed, most often, by a series of destinations, roads, or adjacent towns.

These decoders of the fast-approaching highway interchange, however, slip quickly behind the driver. GPS systems help, of course, but even as the driver begins to navigate in the widened lanes and prepares to change sometimes multiple lanes and then to maneuver to a tightly spaced exit ramp and then into a complex of surface streets to join ongoing traffic, decisions have to be made in seconds. Hesitating in maneuvers can lead to weaving, perhaps the most challenging feature for highway ramp designers to combat. Unless the driver is familiar with the highway system, decisions about where to go and when are complicated by the potential for anxiety and confusion in what can quickly become a living maze. Maneuvering through interchanges requires maximum driver attention and focus. More than 20 years ago, highway engineers in cooperation with a variety of medical commissions gathered data on the human factor involved in engaging highway interchanges and ramps and found a number of telling signs to indicate driver panic: dry lips, accelerated heartbeat, the release of adrenaline, sweaty palms, and uneasy stomach. The science and engineering of highway exchanges must take into consideration not only traffic flow requirements, local politics, cost effectiveness, supporting infrastructure conditions, business and industrial development, and environmental topography, but also the mental and emotional variables in the hundreds of thousands of drivers who will navigate the system over its decades of use. These variables might also include problems such as driver distractions (food, cell phones, music, other riders), lack of driving experience, and/or advanced age.

Basic Types

The Federal Highway Administration in conjunction with individual state departments of transportation and transportation engineers, in

approaching the design or upgrade of any highway interchange, must balance the need for efficiency and speed with safety and ease of use even as, given the ever increasing volume of traffic in major metropolitan areas, these interchanges expand, growing ever more complex. Although there are more than a dozen model types for highway interchanges, considerably more if hybrid models that bring together elements of multiple standard designs are considered, there are three basic models that give engineers and surface transportation planners options, each labeled by their geometric shape if seen from above.

The diamond. Law prohibits intersections on freeways. So to direct traffic onto the freeway, the diamond interchange permits the access of freeway traffic to minor surface roads or vice versa without interrupting the freeway's traffic flow. The interchange of a freeway and a surface street typically involves four one-way ramps: two in each direction, one to allow deceleration for the exit, the other acceleration for the access. The diamond interchange is the most basic and hence cost-efficient interchange design and one of the most widely used in interchanges involving relatively light traffic. The original intention of the diamond interchange was to make unnecessary traffic lights, as even relatively light traffic would overload the traffic light's efficiency. The freeway is separated and elevated from the surface street. Freeway thru traffic moves across the interchange unimpeded typically on a flyover, or overpass. Drivers exiting the interchange from either direction would access an off-ramp that runs directly to the surface road, essentially serving as the on-ramp, making the diamond shape. Where the ramps meet the roads are usually traffic lights or, depending on traffic flow (when the diamond interchange is used in less clogged rural interchanges), stop signs. But traffic running back onto the freeway is left unrestricted and able to merge. The problem with the diamond design has been in the movements between lanes as traffic lines attempt to navigate the merges.

The cloverleaf. By far the most familiar interchange (and among the earliest conceptual, the first patent for the four-leaf clover design was drawn before World War I), a cloverleaf is most often a two-level system that connects a freeway and surface street

using eight ramps and four loop ramps that handle all left-hand turns, those tight clustered ramps giving the interchange the cloverleaf look. To go left, vehicles first cross over or under the road they want to access, then bear right onto a sharply curved ramp that loops at roughly 270 degrees to complete the merge onto the interchanging road from the right and then actually crossing the route just departed. Thus, in a classic cloverleaf interchange traffic need never stop. In essence, drivers turn left by turning right until they are heading in what was left. In addition, cloverleaves were relatively inexpensive to construct because they required only a single bridge to handle multiple directional traffic, but the cloverleaf system required a significant land investment to provide the appropriately banked curved access roads.

In addition, cloverleaves demand precision lane maneuvering (they are not designed for traffic signs or stoplights) and weaving is a constant pressure because there is most often a very limited driving distance (often less than a half mile) between the on ramp of one cloverleaf loop and the off ramp of the next. Thus vehicles exiting the highway are often forced to cut off vehicles that just merged onto the highway. Safe driving spaces become significantly problematic, and traffic necessarily slows to accommodate the maneuvering, and there are other problems. Given the necessarily banked exit ramp network, larger vehicles, particularly loaded trucks, are given to tipping over when they approach the exits if they come off the highway at excessive speeds. Given the merging system, traffic snarls are common. Thus cloverleaves belong generally to older transportation system designs and are for the most part now constructed only in relatively low-traffic flow areas, such as suburbs or in towns.

Many existing cloverleaves have been radically modified with elements of the diamond interchange, reconstructed with ramps connecting now to smaller roads that parallel the highway, called collector-distributor roads, that in turn help relieve traffic, ease the confusion, and minimize driver error as the parallel roads can be maintained at a much slower speed limit (often 40 or 45 miles per hour), which reduces the hazards of cloverleaf exiting when vehicles move at higher speeds.

The stack interchange. In the increasingly dense population centers, interchanges must network two

The five-level stack interchange, known as the High Five Interchange, was completed in 2005 in Dallas, Texas. Its design includes reversible high-occupancy vehicle lanes as well as 37 bridges. Its highest points are as tall as a 12-story building.

major highways, rather than a major highway and a lesser surface street. The stack accommodates that larger conceptual. The stack is a massive (and often intimidating) complex of two pairs of left-turning ramps stacked at an imposing height in a network configuration above, below, or even between the two interchanging highways. Because all left-handed turns are executed on flyovers or underpasses, the traffic choreography in a stack interchange can be quite busy, but because the traffic is moved to the left using flyover ramps and underpasses, there is no need to weave, eliminating one of the most persistent safety hazards in interchange design. A stack interchange can be far more expensive to construct, require more time for construction, and take up considerably more acreage than more conventional interchanges, but it can also be far safer.

The look of stack exchanges can become part of the aesthetics of a postmodern city. The first

completed stack interchange, opened in Los Angeles more than 60 years ago, featuring seven bridges and 22 lanes, has become one of the most photographed images of the city; the interchange's imposing criss-cross hatch of flyovers and ramps and its nearly-constant whirl of traffic in tightly patterned dedicated lanes has come to represent the raw energy of the city and has figured prominently as the backdrop for dozens of films and television shows, valued for its industrial aesthetic, its elegant simple lines and intricate maze-like feel. But the stack interchange is not universally admired—residents who have to deal with the visual impact of the monolithic interchange construction on a daily basis often wage significant public campaigns to prevent stack interchanges from even being built.

New Developments

Perhaps the most exciting development in interchange design in the 21st century is the diverging diamond, which addresses the problem with lane crossing in high-volume diamond interchanges that involve traffic trying to access major highways and thru traffic maintaining their lanes on minor streets. Rather than compel individual cars to maneuver across lanes, the design simply shifts the entire lane of traffic.

The divergent diamond provides a series of synchronized traffic signals that actually send motorists for a few seconds to the opposite side of the road in which they are heading before moving the entire lane back to the other side in a kind of criss-cross design, and there permitting entrance traffic to the highway or thru lanes. Vehicles no longer cross opposing traffic lanes, which (barring traffic accidents or unanticipated conditions) allows for unrestricted movement through the interchange (what designers call “green time”), easing congestion and making the interchange far safer to navigate.

The design, of course, can throw drivers as they must move even briefly away from where they want to drive—in fact states that have already installed these interchanges have provided extensive YouTube animation to help explain to drivers the concept and operation of the interchange. Because the interchange does not require extensive construction—it can use any bridge and ramp system already in place—and because, in turn, the

construction time is minimized, the diverging diamond is considered the critical key in new interchange design.

Highway Interchanges

A highway interchange is a type of road junction that allows highway traffic to pass through the junction without intersecting with other traffic. This is usually accomplished with grade separation, the construction of transportation routes at different heights for the purposes of avoiding mutual disruption. In this sense highway interchanges are a descendent of grade-separated railroad junctions, which originated to prevent road traffic from intersecting with the rails. Interchanges are an alternative to the use of traditional intersections with traffic lights or four-way stop signs, because with the higher speed and more dense traffic of highways, stops are more likely to cause traffic jams, and accidents caused by those who run the stop or fail to brake in time are both more likely and more severe.

A complete interchange includes sufficient exit ramps (which lead traffic onto the intersecting or proximate road) and entrance ramps (which lead traffic onto the highway) to provide access both to and from all directions, which generally means

either four ramps (when intersecting with an ordinary road) or eight ramps (when intersecting with another highway). Interchanges can become complicated when multiple roads are involved, when highway exits and on-ramps are proximate, or when multiple grade separations are used within a short distance, all of which can create confusing traffic patterns, increase the amount of traffic that must change lanes, or increase the complexity faced by merging traffic.

There are a number of different highway interchange designs, some of which are meant for specific numbers of roads or other local conditions. One of the earliest developed was the diamond interchange, generally used for a highway crossing a more minor road. In such interchanges, the highway continues over the road via a bridge, while off-ramps diverge at a slight angle to meet the intersecting road and become an on-ramp back onto the highway on the other side.

This is one of the simplest forms of interchange and does not considerably add to the space needed for the roads, especially compared to more complicated interchange systems. It remains common throughout the rural United States and in many suburban areas. Moderate variations on the diamond design include the double roundabout, which combines the basic idea of the diamond interchange with the use of two roundabouts (one for each direction of traffic), which is used on several western interstates as well as in Minnesota; the tight diamond, a diamond interchange used in urban areas and other places with insufficient right-of-way; and the dogbone interchange, which uses modified roundabouts that don't form a complete circle.

Areas with heavy traffic may require other interchange types, with additional lanes for turning. In urban areas a directional interchange is often more common. A directional interchange, also known as a stack interchange or butterfly junction, uses two pairs of left-turning ramps. The design was first used in Los Angeles at the Bill Keene Memorial Interchange, which connects U.S. Route 101 to State Route 110, and opened in 1953.

The Bill Keene Memorial Interchange was designed because local terrain and neighboring buildings made it infeasible to construct a cloverleaf interchange, which was the default design of the time and still frequently in use. Cloverleaf

A cloverleaf interchange loops through landscaping near Cologne, Germany. The cloverleaf design was first popular in Europe and Latin America; the first U.S. version was built in 1929 in New Jersey. Some have since been converted to updated designs.

interchanges had been designed by civil engineer Arthur Hale in 1916, and though considered for earlier interchanges, the first to be built in the United States was the Woodbridge Interchange at routes 25 and 4 in Woodbridge Township, New Jersey, in 1929. Cloverleaf designs had in the intervening time been implemented in Europe and Latin America; in fact, the Woodbridge implementation was based on a plan used in Buenos Aires, Argentina. They are so named because from an aerial view or on a map, their design resembles the symmetry of a four-leaf clover. Each “leaf” is a ramp conducting traffic along a 270 degree turn in order to merge onto the intersecting road (turning left thus requires a right-hand turn onto this ramp).

Interchanges which use the cloverleaf design but have fewer than four ramps forming “leaves” are considered jughandle interchanges. Cloverleaf interchanges predated the development of the interstate highway system in the 1950s and were

accordingly the most popular interchange design during most of the time when that system was being built. Other than space considerations, which the aforementioned directional interchange addresses, their major drawbacks are the traffic complications—known as weaving—caused by exiting and entering traffic using the same lane, and the possibility of trucks (because of their different center of gravity and weight distribution) toppling when traveling the loops at illegally high speeds.

For those reasons and others, some original cloverleaf intersections have since been converted to other designs. An increasingly popular choice is the single-point urban interchange (SPUI), a modification of the diamond interchange, which was designed for heavy traffic flow. Unlike a normal diamond interchange, a SPUI allows opposing left turns to occur simultaneously, and a single set of traffic signals is sufficient to control traffic.

The first SPUI was built in Clearwater, Florida, in 1974, and became popular because of its space efficiency, though a conventional (and cheaper) diamond interchange without traffic signals is sometimes preferred. SPUIs require a very large expanse of pavement, and although there is an obvious advantage to allowing simultaneous left-hand turns, left-hand turns are also the most frequent source of collisions. This collision problem has been addressed by the development by engineer Vener Tabenero of upstream signalized crossovers, which relocate left-turn lanes and use traffic signals to control criss-crossing lanes, which avoid collisions.

SPUIs can also be difficult to keep clear of snow in the winter, though this has not prevented their widespread adoption in northern snow-prone states like Connecticut (which uses a SPUI at the junction of Connecticut Route 111 and the Merritt Parkway), Idaho, Indiana, Michigan, New Hampshire, and New York. Even Alaska uses several SPUIs, including two on the Johansen Expressway in Fairbanks.

Highway Landscaping

Highways are a form of transportation infrastructure. As such, they are part of an integrated system that also includes electricity lines and lighting, drainage and runoff systems, and increasingly, automated incident detection systems. Landscaping of highways has an aesthetic component, which aims to minimize the impact on the environment through restricting the effect of noise and air pollution. It also has a safety component, as careful landscaping can reduce the threat of snowdrifts or flooding and can also help stimulate the minds of drivers, thereby reducing the dangers of driver fatigue.

Landscaping also has a role in tourist promotion, sustainable development, environmental protection, and wildlife conservation. Because highways are customarily administered by the public sector, transportation infrastructure provides a public good, and the system of highway landscaping will also incorporate the issues of contracting the tendering, monitoring, and evaluation of performance. Landscaping projects need to be planned for the future, and existing projects must be maintained and improved where necessary.

Aesthetic Issues

The aesthetic issues involved with highway landscaping should incorporate perspectives from both road users and those by whom the road passes. Road users include drivers and passengers. Drivers have an important task and should not be distracted too much—there have been reports that accidents have been caused by large roadside billboards bearing particularly striking images. Where landscaping has contributed to the production of a site of particular

beauty or interest, therefore, it can be better to use road signs to guide drivers to parking spaces where they can observe the scenery in a safe manner—this also represents a retail opportunity, of course. In areas of spectacular scenery, for example, in parts of Switzerland, it is possible to integrate tourism management with highway and traffic management by routing tourist vehicles to designated pathways where the experience can be maximized and the intrusion minimized. In environmentally sensitive areas, tourists can be funneled into mass transit systems that use equipment that reduces the negative impact on the environment.

It is also possible for the consideration of the aesthetic appeal of a highway to be used to improve the appearance of industrial or suburban areas through which the highway passes by an encouraging or incentivizing approach to environmental management. This can contribute to better quality of life for many people in the vicinity of the landscaping project and also to economic regeneration of depressed areas. When combined with the use of alternative energy, highways can even promote sustainable development.

From the perspectives of residents whom the road passes, the aesthetic component relates to hiding the sight and sound of the traffic, since these represent forms of pollution and can also have a negative impact on property values—this is important in that it will promote local resistance to the construction of highways. On the other hand, it is possible for property values to rise in some cases when the landscaping improves the quality of life and the proximity of the highway represents an important locational advantage.

The aesthetic component also merges with the safety issue when highways are built close to or pass through residential areas. Particularly in less developed nations, highways tend to be built at as low a cost as possible and this means there is little if any barrier between traffic and residents, which is clearly a suboptimal situation. During the early period of rapid economic development in South Korea, highways were needed to link places of production with ports providing export services and, to reduce cost, were built without any lighting.

Safety Issues

In terms of road users, landscaping can make a contribution to safety by hindering snow drifts or

flooding and selecting plants and trees for roadside decoration that will not shed slippery leaves on the road at certain times of the year. The exact nature of the risks to be addressed here depends on geographical and climatic factors, as well as to the societal response to them. In Scandinavia, for example, there is an annual threat, often over an extended period, from dangerous conditions caused by the low temperatures and precipitation. However, because this is an anticipated threat about which people have abundant information and the resources to cope, the people generally respond rationally and risks are reduced thereby.

Similarly, in countries with few resources available along the road, as in the case of a number of sub-Saharan African countries, drivers and their assistants have had to become adept at maintaining and repairing vehicles using only the most rudimentary of equipment. However, when conditions are less predictable risks are increased because people cannot respond in such a rational and well-prepared way. In addition, the ongoing crisis of austerity that followed the economic crash of 2008 has accentuated problems by reducing the funds available for infrastructure generally, as the various collapsing bridges in the United States during 2013 have helped indicate.

Wildlife Conservation

Highways offer both threats and opportunities to wildlife as well as to farmed animals. Roads pass through the countryside and may intersect farmland. When this happens, the relevant highway authority may be required to make some provision to allow livestock to cross safely as part of the normal agricultural practice. Depending on the size of the highway and the topology of the surrounding terrain, crossing may be tackled by an overhead bridge or by a tunnel under the road. In some cases, this involves the prevention of the spread of disease. More sophisticated systems may be required in the event of areas of environmental fragility or of special scientific interest. In many developed countries, laws exist and are enforced to ensure that road construction is prevented in areas that hold protected species. In some cases, the application of science can be used to find solutions by landscaping the areas involved so that the flora or fauna can be protected.

Highway landscaping has already improved conditions for some types of wildlife. The regular

movement of traffic confuses earthworms, for example, along the grassy verges and banks and they rise to the surface more often and are preyed upon by raptors that have discovered this new and abundant source of food. The reserved area along the side of the landscaped road can act as a form of nature reserve in which some species can flourish when other habitats have been compromised.

Green Landscaping Issues

As the world has begun to provide increasingly obvious evidence of the impact of global climate change, design and implementation of green technologies has become an ever more urgent issue. To a certain extent, highway landscaping can never be a truly green endeavor because it relies on highways, which not only encourage resource use but make the greater use of resources a profitable and desirable activity.

Nevertheless, it is possible to consider the more efficient use of resources within the landscaping process and, in particular, the choice of materials. Plants and trees absorb greenhouse gases at different rates—mangroves are particularly efficient in this regard—and careful selection and mixing with native plants can help maximize the amount of product that can be recycled or reused. Some products of the landscaping process may be economically valuable.

Highway Planning

Highway and bridge projects implemented under programs administered by the U.S. Department of Transportation's Federal Highway Administration (FHWA) may be eligible for federal funding if the sponsoring transportation agency project or public works organization meets certain standards in compliance with federal law, including conducting an environmental review. The environmental review process includes activities necessary to demonstrate that all potential project-related impacts to the human, natural, and cultural environment have been identified and that the effects of those impacts, such as economic or community benefits, have been taken into consideration before a final decision on the project is made.

In addition, the public must have the opportunity to be included in the project decision-making process as mandated by the National Environmental Protection Act (NEPA) of 1969. Typically, public involvement occurs at the first stage of the highway development process, which is the planning stage. The planning stage is followed by subsequent stages of development/preliminary design, final design, right-of-way, construction, and ongoing operation and maintenance.

It is during the first stage of the highway development process that the project is defined at the state, regional, or local level, based on the scope of the perceived problem and the proposed development solution. The most common types of problems predicated a call for highway development fall under one or more of four broad categories. Structural problems relate to existing physical structure that needs major repair or replacement. Capacity problems involve existing or projected travel demands that exceed available capacity and require increased access to transportation for greater mobility.

Issues related to safety occur when a route experiences an excessive number of incidents and accidents that can be resolved only through physical transformation of the route. Access problems are associated with developmental pressures along a route that make it necessary to reexamine the quantity, location, and physical design of access points. Solutions to all of these types of problems can be put into one of four types of improvement projects: new construction; reconstruction; resurfacing, restoration rehabilitation; and maintenance.

It is essential that all parties involved in highway development agree during the planning stage that a real problem exists, what the specific problem is, and whether the jurisdictional parties are willing to fix it. For example, road access may be identified as a real problem, but the jurisdictional community may prefer not to alter the status quo for fear of associated detrimental effects like increased traffic congestion.

The Government's Role

State transportation departments are required to develop and maintain a statewide, multimodal transportation planning process. The categories of highway improvement needs are defined in alignment with ongoing analyses of roadway pavement conditions and estimates of projected future traffic demands. Each state also is required to conduct inspections of its major bridges every two years and of its minor structures less frequently to determine their structural adequacy and capacity.

A number of states prepare regional transportation plans for multiple counties within the context of the statewide planning process. Every few years, the state selects improvement projects based on the long-range plan and includes them in the Statewide Transportation Improvement Program (STIP).

State efforts are supplemented in urbanized areas through the metropolitan transportation planning process. Metropolitan planning organizations (MPOs) develop their own regional plans, whereas most other areas are subject to the state planning process. The metropolitan planning process involves developing a long-range plan that defines the region's multimodal transportation needs and identifies local funding sources that will be needed to implement the underlying projects. The MPO then prepares a more detailed plan that prioritizes projects for work in the short term. The resulting near-term plan becomes part of a Transportation Improvement Program that is incorporated into the STIP.

Most of the smaller U.S. cities and counties follow a similar process of project determination, cost estimation, and prioritization regarding development projects for the roadways for which they hold primary responsibility rather than the state. The state's Department of Transportation will solicit local input for the STIP but typically does not become involved in the local development project itself.

Factors to Consider During Planning

For any highway development project it is essential that consideration be given during the predesign planning phase to the potential impact that a proposed modification or enhancement might have on the character, capacity, and culture of the surrounding area. FHWA projects must adhere to federal guidelines designed to ensure that planners evaluate possible adverse, economic, social, and environmental effects of proposed highway projects and locations.

The guidelines also stipulate that final project decisions must be made in the best overall public interest, which involves considering factors like the costs of eliminating or minimizing adverse effects of air, water, and noise pollution; destruction or disruption of natural and human-made resources; visual appeal, community unity, and availability of public facilities and services; adverse employment ramifications and tax and property value losses; and detrimental displacement of people, businesses, and farms.

Land use is also a key factor to consider during the highway development planning phase. Land use determines the function of an area's roads. Since land use tends to change periodically in response to growth and development, road function must be adapted accordingly. It is increasingly more common for rural farm access routes to evolve into roadways that service suburban residential subdivisions and commercial businesses. By considering land use during the project planning stage, design standards created in subsequent phases of development can better meet actual and expected changes in traffic character and road function over time.

Planning and Environment Linkages

The FHWA has established a planning and environment linkages (PEL) approach to transportation decision making. The collaborative effort involves considering environmental, community, and economic goals early in the transportation planning process and using the resulting information, analysis, and products developed to enlighten the environmental review process.

The PEL approach provides significant benefits for state and local transportation agencies. It helps build relationships and facilitates interagency integration, enabling all agencies to be more involved at the planning stage and more effective throughout

the decision-defining process for transportation projects. The enhancements to interagency relationships also may help agencies more quickly and easily resolve differences on key issues that might arise as the project moves forward through implementation.

Another benefit of the PEL strategy is improved process efficiencies and potentially faster delivery timelines. By reducing possible duplication of planning and NEPA processes, the PEL approach enables a singular cohesive flow of information among all parties involved. When transportation agencies conduct planning activities armed with information about resource considerations and in coordination with resource agencies and the public, they are more capable of designing transportation programs and projects that best serve the community's transportation needs. As such, the PEL approach ensures that transportation agencies have appropriate tools and information during the highway development planning stage to design better projects and minimize impact to the surrounding human, natural, and cultural environment.

Highway Removal

For most of the 20th century, highway removal was scarcely imaginable. Automotive traffic was growing, and road space was perpetually in short supply. Transportation policy was nearly synonymous with road construction. Only late in the century did a shift in priorities make the removal of roads conceivable, and occasionally even possible. Highway removal is a product of changing beliefs about the value and uses of inner-city land and about the role of automotive traffic in cities.

Changing Priorities

Although some roads slated for removal were considered underused, the growing interest in highway removal reflects changing priorities far more than declining car use. Most of these roads are in urban areas where planners, activists, or developers have foreseen more valuable uses of the land consumed by the highways. The roads were also blamed for dividing communities and for blighting adjacent neighborhoods with emissions, noise, and dangerous traffic. In addition, proposals to remove a road typically reflected a growing belief that cities need to move away from car-centric policies in favor of alternative models of both transport and land use. Proponents of highway removal wish to rebuild city centers on a pedestrian scale and promote investments in mass transit and pedestrian and bicycle infrastructure. They have typically emphasized the value of reconnecting urban spaces—cities to waterfronts, businesses to residential areas, and roads to adjoining buildings.

Typical candidates for highway removal are elevated urban express roads built around the middle of the 20th century to open up congested city centers to free-flowing auto traffic. When these aging roads need major structural repair, it becomes more plausible to argue for the cost-effectiveness of removing or replacing them. Most are in the United States, since far fewer inner-city freeways have been built in other lands. Proposals to remove them have been initiated in part by city officials and in part by citizen initiatives.

An unusually early example is the removal of Harbor Drive in Portland, Oregon, in 1974, and its replacement by a riverfront park. This expressway into the city center, opened in 1943, was a typical mid-century urban highway, although it was

connected to other freeways at only one end, and had been made partly redundant by two newer freeways. Even then, its removal can be attributed to unusual civic leadership. Another unique case was New York's elevated West Side Highway, which had to be closed in 1973 because of structural deterioration and which was eventually replaced by a boulevard—a decision that came only after controversial plans for an upgraded freeway were cancelled in 1985.

The decision to remove a road came more easily where it had never been completed in its full length or had been intended to connect to another road that was never built. (An extreme case is Baltimore's "Highway to Nowhere," which was never connected to planned freeways at either end, and which was partly demolished after 2010.) Among the best-known examples are two from San Francisco. The Embarcadero and Central freeways were both elevated inner-city stumps, never completed, and damaged in a 1989 earthquake, after which the city decided to tear them down and replace them with multiuse boulevards. Other examples of removed freeway stumps from the early 2000s include Milwaukee's elevated Park East freeway, one end of Toronto's lakefront Gardner Expressway, and the Oak Street Connector in New Haven, Connecticut. The Chattanooga (Tennessee) Riverfront Parkway is a case of an underused highway that was downgraded to a narrower, slower street. A similar example is the Robert Moses Parkway in Niagara Falls, New York.

Among the few examples outside the United States is the Cheonggye Expressway in Seoul, South Korea, which had been built through the city center atop the buried Cheonggyecheon River. It was removed in 2003 and replaced with a restored stream, linear park, and streets. In Paris, France, the Seine riverbank expressway from the 1960s has recently been closed in the city center. Both Seoul and Paris closed these roads as part of a comprehensive strategy to reduce inner-city automotive traffic, including transit improvements as well as restrictions on car traffic.

Road Capacity

In nearly all the cases of highway removal, fears of traffic gridlock did not come to pass. Any proposal to remove a highway is certain to attract vehement opposition from those who argue that the result will

be traffic congestion on parallel roads or replacement streets. Such fears are often exaggerated, however, as former freeway users find alternate routes, choose alternate modes, accept slower speeds, or simply drive less. Although critics are correct to note that slower, narrower roads cannot carry as many vehicles per hour as the freeways, they sometimes fail to question their assumption that driving patterns will remain unchanged even when roads do not.

However, some plans to remove hated roads have depended on the replacement of all the lost road capacity. In these cases an ideal solution is a tunnel that frees up land and removes cars without reducing road capacity. The most notable example is Boston's "Big Dig" that buried its elevated Central Artery. That project in the 1990s and 2000s became so notoriously costly (at least \$14 billion) as to discredit this approach. Nevertheless, in 2011 Seattle voters approved a tunnel to replace the elevated Alaskan Way viaduct along the city's waterfront. "Highway relocation" might be a better label than highway removal for these tunnels, as well as for inner-city freeways that have been rerouted away from the city center, as in Oklahoma City and in Providence, Rhode Island.

Effects

Where freeways have been entirely dismantled, they have typically been replaced with boulevards, which trade slower speeds and reduced vehicle capacity for multimodal use, pedestrian access, and direct connections to side streets, sidewalks, and adjacent buildings. Instead of a limited-access motor road, the result is a street—a road integrated into the city, lined with buildings, consuming less space, and freeing up some land for other uses, including new buildings and parks. In most cases, the replacement of demolished freeways has been governed by the principles of "complete" or "livable" streets—the polar opposite of the typical freeway.

Local initiatives are urging the removal of freeways in many more cities, including Toronto; Syracuse, Rochester, Buffalo, and the Bronx, New York; New Orleans; Louisville, Kentucky; Nashville, Tennessee; Washington, D.C.; Trenton, New Jersey; Cleveland, Ohio; Baltimore, Maryland; Hartford, Connecticut; and St. Louis, Missouri.

Highway Safety Barriers and Traffic Barriers

Each year, more than 6,840,000 people in the United States are in roadway accidents. Annually, accidents injure 3,511,000 people and kill 41,907. Highways are dangerous, and until the middle of the 20th century, the assumption was that the death toll was inescapable because these deaths were caused by driver error. Only in the 1960s was an effort begun to make highways safer by reducing or eliminating hazards on roadsides or by placing barriers between hazards and errant vehicles.

The barriers are not foolproof nor a total solution, as fatalities remain high. As of a 2003 report, 38 percent of fatal crashes nationally involved single vehicles leaving the road and either hitting a fixed object or overturning. The United States recorded 821 fatal head-on crashes due to median crossovers on the interstate system in 2006.

Traffic barriers such as guardrails and safe highway drainage designs keep the numbers from being even higher. To ensure uniformity across jurisdictions, the federal and state governments publish standards for placement and design of signs, posts, and other barrier technologies. The federal *Manual on Uniform Traffic Control Devices* (MUTCD) specifies minimum offset distances for signs, and mandates breakaway, yielding, or barrier-shielded

signposts in clear zones. A clear zone is an area near the driving surface that is free of hazards. Clear zones can vary—from as narrow as less than 10 feet to as wide as 30 feet, depending on speed, traffic volume, roadway geometrics and classification, and slope. Even low-volume roads have to conform to the clear zone standards. A clear zone is a flat and unobstructed area off the edge of the road where errant vehicles can recover. Width depends on traffic volume, intended speed on the road, and embankment slope.

Similar standards apply to temporary signs in work zones. For rural roads with only local traffic the standard may be waived because the assumption is that the users are familiar with the road hazards and adjust accordingly. Iowa began in 1989 flattening driveway slopes on farm to market roads, approximately 15,000 of them by 2003. Iowa also developed a public information campaign in 2002 and developed a detailed inventory of all county roadsides, as well as a mitigation plan for obstructions identified in the inventory, including removal, relocation, and remodeling to incorporate breakaway and barrier features.

Purposes

A forgiving roadside allows a driver to err, gives that driver time and space to correct the mistake, and eliminates as many as possible hazards to the errant driver. Among the hazards are bridges, trees, mailboxes, poles, guardrails, embankments, and ditches. Anything that interferes with the safe halting of the vehicle or its return to the roadway under control is a hazard.

Barriers are routinely employed to block collisions with roadside signs, but this is not necessary in all cases. Small signs or signs with breakaway posts are less of a danger than a barrier would be. Obstacles outside the clear zone also do not require barriers (the clear zone or horizontal clearance or clear recovery area is the lateral distance on a recoverable slope that a vehicle can travel off the roadway and still return to the roadway safely; it is contingent on speed limit and type of roadway) as long as there are no steep slopes or fixed obstacles in the clear zone.

The purposes of a barrier are to keep vehicles from departing the roadway and from colliding with walls, buildings, drains and culverts, and other dangerous obstacles. Placed beside the road, they block

vehicles from climbing steep slopes or driving into deep water. On medians of divided highways they block vehicles from entering the opposing lanes, thereby reducing the risk of head-on collision. A barrier serves to limit the severity of an accident (as when a vehicle or vehicles leave the roadway) only when hitting the barrier is a lesser harm than leaving the roadway. Considerations for designing the appropriate barrier include traffic volume, speed, distance to the hazard from the roadway, and distance to the barrier from the roadway. Types of barriers include longitudinal barriers such as guardrails and median barriers and crash cushions.

Bridge barriers are higher than roadside barriers because they have to prevent buses, pedestrians, cyclists, and trucks from rolling or vaulting over the barrier and off a bridge onto a railway, roadway, or river. Multirail tubular steel barriers or reinforced concrete barriers and parapets are used for this purpose.

Median Barriers

Because modern highways are commonly divided by medians that can be crossed by an errant vehicle in split seconds, there is a need to reduce the likelihood of said errant vehicle moving across the median and into oncoming traffic. Also, in construction zones with traffic flowing in both directions at high speed in close proximity, median barriers help reduce head on collisions. Barriers made to withstand contact from either side are called median barriers. Median barriers are designed to prevent head-on crashes from a vehicle leaving its lane and crossing into oncoming traffic. Roadside barriers protect from one side, but median barriers must withstand contact from either side.

Median barriers, the longitudinal barriers that separate opposing directions of traffic on a divided highway, do not reduce the frequency of roadway-departure crashes, but they do help keep a median crash from being a head-on collision. At highway speeds a vehicle can cross the median and collide head-on in the length of a yawn. Barriers must be designed and placed properly if they are to protect oncoming traffic and the occupants of the straying vehicle at the same time.

Barriers can also come in a variety of configurations and materials. Selection criteria include types of vehicles using the highway, configuration of the roadway, and the potential severity of a head-on

due to median crossover. For most circumstances, standard barriers that can redirect cars, vans, and trucks will serve. Longitudinal barriers are primarily intended to redirect vehicles and keep them on the roadway.

However, high traffic volumes and speed or a large number of heavy trucks on a roadway of unusual configuration or in a difficult environment can demand more stringent measures. Rigid barriers are commonly made of concrete. Initial installation is expensive, but concrete offers relatively low cost over the life cycle, virtually no maintenance, and a good safety result. Because they absorb the least energy of the three categories of barrier, concrete barriers may produce more severe injuries, but overall, they are a highly effective mitigation device in high-volume and high speed roadways. They also work well in high truck traffic environments. Concrete barriers are also appropriate when median width precludes installation of other barrier types.

A concrete barrier has little or no flexibility, redirects vehicles back to the shoulder or their lane, and works best where two-way traffic occurs in close quarters and there is no room for a median. However, a concrete barrier is not necessarily best in all situations. If there is a realistic opportunity that a driver can get off the road onto a level median and recover, then that is preferable to colliding with an inflexible concrete wall. If the median or shoulder is not large enough, then concrete is the better choice. Criteria for location and type of barrier include accident history, prevailing speed, volume of traffic, curves (road geometry), cost of installation and maintenance, grade and slope, and amount of shoulder and median space. Environmental concerns and the characteristic of the given type of barrier are also factors.

The semirigid barrier is more commonly known as a guardrail or guiderail. It involves segments of metal railing held together by posts and blocks. It works well in traversable medians with minimal cross slope or grade change. These barriers are cheaper than rigid barriers but are more difficult to install in poor slope or difficult grades. They also have to be repaired or replaced after a collision, so life cycle cost may be higher. Guiderail systems absorb energy during crashes and move or deflect on impact.

Cable barriers consist of several steel cables connected by posts. They minimize impact forces on

the vehicle and occupants and absorb most of the kinetic energy. They are usually the cheapest to install, but they require maintenance after a crash. Still, they are the most forgiving and versatile of the barrier types.

One type of high-tension cable system design reduces deflection and resists impact forces. This type of system is easier to repair if a post is damaged and is also more practical in narrower spaces. Cable median barriers allow a vehicle to stop without reentering traffic, provides for water to flow underneath, works well with wide medians, and flexes up to 12 feet.

Regardless of the type of barrier chosen, ease of maintenance is extremely important. A single crash may damage several posts or sections of a barrier. Until repair is completed, the barrier is inadequate for protection against any crossovers.

Roadside Barriers/Guardrails

Danger comes at the side of the road as well as in the median. Traffic barriers are routinely placed near steep slopes close to roadway edges, at bridge

ends, at culverts or drainage crossings with vertical or steep drops, and near light poles or large signs or other roadside fixtures that may constitute hazards. Roadside barriers protect traffic from such hazards as steep slopes that might cause a rollover, fixed objects such as bridge piers, and bodies of water.

Initially, barriers had no special modification at their ends so vehicles colliding with a blunt end could either stop sharply or have a steel rail enter the passenger compartment. Often the result was severe injury or death. To correct the problem, barriers were modified with the addition of an end that brought the barrier to the ground. This style ended the problem of penetrations but, because it formed a ramp at barrier's end, led to occasional instances of vehicles vaulting into the air or rolling over.

The next iteration was incorporating energy absorbing terminals, including a large impact head to receive the bumper or vehicle frame, which drives the impact head back along the guiderail, allowing contact energy to dissipate as the steel rail bends or tears. Another approach is to curve the guiderail back sufficiently that the terminal is not susceptible to head-on contact, preferably because it is embedded in a cut slope or hillside.

Rail end treatments provide effective deflection and absorption of oncoming traffic without spear-ing. Rail end treatments are available in a wide variety of end types, including flares, question marks, 90-degree turns, and several identified by federal standard number or letter (ET2000, ET-Plus, XRT-350, SKT-350, and Regent-C.) Further strengthening the absorbent capability of guardrails are blockouts, spacer blocks that separate the rail from the post; spacers are no longer steel because plastic and wood are safer.

The National Crash Analysis Center (NCAC) has made great strides in determining the safest guardrail posts for highway use. The NCAC developed computerized crash simulation finite element (FE) models, which were used in combination with traditional crash testing to determine the optimal post for highway use.

Finite elements recreated the explicit geometry, weight, inertia, and mass of each guardrail component. Comparisons to full-scale crash tests have validated the accuracy of finite element models. These tests helped determine the optimal choice of blockouts, steel gauge, and post gaps for optimal guardrail performance.

The rounded end of a guardrail in Burtonsville, Maryland, in 2007 is painted with a reflective coating. The coating used was a bright yellow to make it more visible at night.

Barriers are defined as flexible, semirigid, or rigid, based on amount of deflection when struck by a vehicle and what means the barrier uses to resist the impact. The American Association of State Highway and Transportation Officials (AASHTO) *Manual for Assessing Safety Hardware* is the current U.S. standard, replacing the Federal Highway Administration NCHRP Report 350. Flexible barriers, including cable and weak-post corrugated guiderail systems, dissipate energy through tension in the rail elements; deformation of the rails, posts, and vehicle body; and friction between rail and vehicle.

Semirigid barriers are the box beam guiderail, three-beam guide rail, and heavy post blocked-out corrugated guiderail. They are sturdier than flexible rails and dissipate impact energy similarly but can spread impact over a greater number of posts because of the rigidity of the tube.

Rigid barriers are usually made of reinforced concrete formed into a shape that guides the vehicle along the length of the barrier rather than allowing the vehicle to collide directly with the barrier. The vehicle crumples as it slides along the barrier, dissipating collision energy.

F-shape and Jersey (originally a type developed by the New Jersey highway department but now a generic term) concrete barriers are also shaped so that tires will ride up the lower section, causing the vehicle to lift and slow. Low-angle or low-speed impact may produce only minimal vehicular damage, but for small cars there is a significant increase in risk of rollover.

Other barrier types are constant slope and concrete step, and barriers can be either smooth concrete or have faux stone or stone finishes for esthetic reasons (these barriers have vertical faces so cars cannot climb them.)

Guardrails flex up to 3 feet, allow water to pass underneath, give drivers some control after impact, and work in areas with steep slopes. Galvanized guardrails can be either 12-gauge (class A) or 10-gauge (class B) steel, most commonly in the form of the W-beam, rails roll-formed into a W-shape to catch a car bumper. This type of rail creates a long barrier whose purpose is to minimize damage from a run-off-road collision by absorbing and dispersing impact over distance. W-beam guardrails are economical and effective.

Guardrail posts on state and federal highways have to conform to a higher standard based on an

NCHRP 350 report. State and federal highway post regulations have recently been updated after an NCHRP 350 report determined that wooden posts provide increased safety over steel posts. Guardrail post safety is a concern of the National Crash Analysis Center (NCAC), which uses computerized simulations and traditional crash testing to determine which post is best. The NCAC tests also determine the best steel gauge, post gaps, and blockouts.

Prevention of Flooding

Heavy rains can cause flooding that impedes or endangers traffic. When possible, culverts route water from the roadway surface either through the embankment or by means of a channel. Culverts have to be strong enough to handle road traffic and an overburden of earth. Culverts must offer minimal risk of damage to property or traffic due to failure. Drains empty the roadway of water so that traffic will not be hampered. Drains serve where culverts are impractical, usually in heavily built urban areas. Drains can incorporate cuts into the curb, grates, slots, or a combination of the three.

Temporary Barriers

Barriers are essential in permanent configurations such as the divided highway or the traffic lane with an insufficient clear zone due to natural obstacles along the roadside. Additional purposes for safety barriers come with more temporary situations. Temporary barriers are different in style and purpose from permanent ones. Traffic barriers to route vehicles and pedestrians clear of danger come in many forms, and they are useful for blocking access, controlling crowds, diverting traffic, and completely closing roads. They range in size from cone to temporary wall, and when filled with water are quite strong and stable. Other options include modular and plastic expanding barricades. Other names for traffic barriers are crash barriers and Armco barriers (a genericized trademark of AK Steel, formerly Armco.)

Crash barriers serve not only to restrict errant vehicles but also to protect vulnerable areas from said vehicles. Crash barriers protect pedestrian zones, fuel tanks, school yards, and the like.

For work zone hazard protection, movable barriers are preferred. Temporary concrete barriers are one type. Another is the water filled barrier, steel reinforced plastic boxes that can be linked together longitudinally. When filled with water they provide

a substantial wall. They are convenient because they do not require heavy lifting equipment for placement, but they are not suitable for freezing weather.

Impact attenuators reduce risks due to wider hazards that are not amenable to protection by the single-sided traffic barrier. Also known as cowboy cushions, crash cushions, or crash attenuators, impact attenuators absorb kinetic energy and redirect vehicles away from hazards or road construction equipment and crews. They are located in front of fixed objects such as gore points, Jersey barrier introductions, or overpass supports. Temporary types are common on road construction.

Snow plows and other road equipment incorporate truck-mounted impact attenuators. Attenuator trucks have to maintain a specified distance from workers or machinery, particularly in mobile work zones. Rows of sand or water-filled barrels are one type of attenuator that works by momentum transfer as the sand or water absorbs the speed of the colliding vehicle. Newer attenuators of the material deformation style use crushable material to form a crumple zone to absorb energy. Material deformation style also includes corrugated steel guard rail that flattens on impact or a steel box beam that splits to absorb the blow. Some attenuators force a steel cable or strap through a slot or tube to convert kinetic energy into heat.

The widely used Fitch Barrier is a sand- or water-filled plastic barrel, commonly yellow with a black lid. In a triangular configuration at the end of a guard rail between a highway and exit lane (the gore), these barrels are arranged so each successive one has more sand. Vehicle contact shatters the barrels, and the scattering sand dissipates the energy, causing a smooth deceleration rather than a violent collision. Since they were developed by race car driver John Fitch in the 1960s, they have saved up to 17,000 lives.

Conclusion

Barriers are designed to minimize injury to vehicle occupants but, being mostly immovable objects, they do sometimes cause injury. Therefore, they should be used only when the alternative damage from contact with the obstacle the barrier blocks is probably worse. Rather than adding a barrier to an obstacle, the better course if feasible is to remove or alter the obstacle. Traffic barriers undergo simulated and actual crash testing to guarantee effectiveness

and safety, but no test can cover every scenario. They can, however, minimize probability of damage by ensuring that the barriers perform at a satisfactory level to protect vehicles and passengers and other users of the roadways.

Barriers alone do not guarantee safety. Additional measures include rumble strips to wake drivers straying out of the lane, speed enforcement, and speed limits. And the driver has an obligation to be alert, maintain the vehicle, adjust for weather and traffic, and not drive under influence of drugs or alcohol.

Highway Trust Fund

The Highway Trust Fund (HTF) was established by the Highway Revenue Act of 1956 as a mechanism to finance an accelerated highway program (including construction of the Interstate Highway System) by ensuring a dependable source of financing for the Federal Aid Highway Program (FAHP). Though federal motor fuel and motor vehicle taxes existed before the creation of the HTF, their receipts were deposited into the U.S. government’s General Fund and had no specific relationship to federal funding for highways.

The Highway Revenue Act directed the deposit of revenues from certain highway-user taxes into the newly created HTF for use in financing programs enacted in the Federal Aid Highway Act of 1956. Taxes dedicated to the HTF have continuously been extended by Congress and the HTF has become the primary source of federal funds for the FAHP.

History and Key Legislation

Before 1956, funding for the FAHP came from the General Fund of the Treasury. Highway-user taxes, such as those on motor fuels and automobile products, existed but were not linked to highway funding. However, the Federal Aid Highway Act of 1956 significantly expanded the FAHP, which required more extensive and consistent funding if the states were to adequately plan for the longer term. To make the FAHP self-financing and to provide longer term continuous funding, the Highway Revenue Act of 1956 established the HTF and dedicated 100 percent of federal motor fuel tax receipts and a certain percentage of receipts from highway-user taxes (such as on tread rubber, tires and inner tubes, trucks, buses, etc.). Furthermore, this legislation authorized an increase in the federal gasoline tax from 2 to 3 cents per gallon (cpg).

Originally created as a temporary trust fund to provide funding for interstate constructions, the HTF and the taxes dedicated to it have been continuously reauthorized and extended. However, while the basic principle of HTF as a fund with dedicated revenues from taxes paid by highway users has remained in effect, the tax rates and allocations of tax revenues that originally underpinned the HTF have changed over time.

Major revisions occurred as a result of the Surface Transportation Assistance Act of 1982 and the Deficit Reduction Act of 1984, which increased fuel tax rates and established a Mass Transit Account in the HTF to receive a portion of the fuel tax revenues. Another increase of 5 cpg was enacted as part of the Omnibus Budget Reconciliation Act of 1990 (OBRA 90), which also fundamentally changed the revenue structure underpinning the HTF. Whereas previously all revenues from the federal motor fuel tax went into the HTF, only half of the revenues from the 5-cent increase would now go into the HTF and the other half would go to the General Fund of the Treasury for deficit reduction.

The General Fund portion of the tax was imposed on a temporary basis and scheduled to expire on October 1, 1995. The Omnibus Budget Reconciliation Act of 1993 extended the temporary General Fund tax increase of OBRA 90 but directed the revenues toward the HTF. This legislation also increased the tax by 4.3 cpg, bringing the gasoline tax to 18.4 cpg, with the incremental revenues going to the General Fund for deficit reduction.

The Taxpayer Relief Act of 1997 subsequently redirected the 4.3-cent General Fund tax to the HTF effective October 1, 1997. This was the last change to the federal gasoline tax rate. The motor fuel tax underpinning the HTF was most recently extended through September 30, 2016, by the Moving Ahead for Progress in the 21st Century Act (MAP-21).

Structure and Revenue Sources

The HTF is a financing mechanism established by law to account for federal tax receipts dedicated or earmarked for specific types of transportation expenditures. Originally, the HTF focused solely on highways, but this changed when the Mass Transit Account was created within the HTF and a portion of HTF revenues set aside in the account. Although

never legally described and named, the portion of the HTF outside the Mass Transit Account has been called the Highway Account and it receives all HTF receipts not specifically designated for the Mass Transit Account. In 2011, the gasoline tax was 18.4 cpg and the diesel tax was 24.4 cpg. Of both taxes, 2.86 cpg went into the Mass Transit Account and 0.1 cpg went into the Leaking Underground Storage Tank Trust Fund. The remainder was deposited into the Highway Account.

Tax revenues directed to the HTF are derived from excise taxes on motor fuel and truck-related taxes (specifically on truck tires, sales of trucks and trailers, and heavy vehicle use). In fiscal year 2011, total receipts for the HTF totaled \$36.9 billion, and expenditures were \$44.5 billion. Gasoline taxes composed 64 percent of total receipts for the HTF, and taxes on diesel and special motor fuels composed 25 percent. Truck-related taxes contributed 8 percent of revenues, with a large portion of this revenue generated by the tax on sales of trucks and trailers.

In terms of the distribution of expenditures, 81 percent of HTF expenditures were for programming by the Federal Highway Administration, 16 percent (mostly from the Mass Transit Account) were by the Federal Transit Administration, and the remaining expenditures were by the Federal Motor Carrier Safety Administration and National Highway Traffic Safety Administration.

All revenues from the three truck-related taxes go into the Highway Account of the HTF. The first is the truck tire excise tax, which is imposed on truck tires with a maximum load capacity over 3,500 pounds. This tax is based on the maximum load capacity at the rate of 9.45 cents for every 10 pounds over 3,500 pounds. The truck and trailer sales tax applies to the retailer's sales price of tractors and trucks over 33,000 pounds gross vehicle weight (GVW) and trailers over 26,000 pounds GVW.

The tax of 12 percent also applies to parts and accessories sold in connection with the vehicle sale. The heavy vehicle use tax is an annual tax on the ownership of trucks that weigh over 55,000 pounds GVW. For trucks between 55,000 and 75,000 pounds GVW, the tax amount is \$100 plus \$22 for every 1,000 pounds (or fraction thereof) over 55,000 pounds. For trucks over 75,000 pounds GVW, the tax is \$550.

Distributions and Funding Challenges

Each state's highway users contribute to the HTF by paying motor fuel taxes and other highway-related user taxes. These funds are subsequently allocated from the HTF to the states according to a mathematical formula that attempts to relate resources to needs. A return ratio can be calculated that compares the funds paid into the HTF through revenues collected by motorists in each state with the state's total apportionments and allocations from the HTF.

A ratio of 1.00 indicates that a state receives the same amount of apportionments and allocations from the HTF as it contributes into the HTF. A ratio of less than 1.00 indicates that the state receives less from the HTF than its highway users contribute in motor fuel taxes (a donor state), while a ratio greater than 1.00 indicates that the state receives more than it contributes (a donee state). Donor states are located mostly in the southern and Great Lakes regions, while donee states are clustered mostly in the New England and mid-Atlantic regions.

One of the challenges to the HTF is that states, on average, receive more federal-aid funds than they put into the HTF. Since 1956, the return ratio for all states was 1.15; states received 1.15 times more funds than they contributed to the HTF. In addition to the problem of dispensing more funds than are paid into the HTF, the balance in the HTF has continually been a point of controversy. Given the nature of the FAHP as a reimbursable program, there is always excess cash in the HTF that is not needed for immediate use but that will be needed to reimburse the states as they submit vouchers for authorized work in the FAHP.

However, spending from the HTF has exceeded its revenues, and since 2008 the HTF has received almost \$35 billion in transfers from the General Fund. These transfers were \$8 billion in 2008, \$7 billion in 2009, and \$13.6 billion in 2010. The HTF also received \$6.2 billion from the General Fund in November 2012.

Highway Tunnels

Although it took engineers hundreds of years, tunnels came of age in the 19th century. Tunnels are, essentially, horizontal hollowed passageways that are cut through soil or stone. Tunnels provide solutions to traditional modes of transportation, whether it is necessary to traverse a physical barrier such as a mountain or create a solution to a modern problem such as too much traffic congestion. Tunnels fall under the jurisdiction of the Federal Highway Administration (FHWA) of the U.S. Department of Transportation (USDOT). Through advances in technology, the utilization of underground space has expanded tremendously within the last decade.

When building tunnels, planners must also take into consideration many safety concerns regarding workers, the materials through which they are

passing, and the unique geological conditions in which they're building.

Planning and Building

Although planning for and building different types of tunnels varies dramatically, there are some universal steps that can be applied to each project. Tunnel experts of the FHWA report that major aspects for consideration are: determining the alignment, clearances, and size of the bore; conducting a geotechnical investigation to determine the types of materials that the tunnel will be passing through; determining the probable construction method; investigating drainage and lining requirements; organizing safety provisions such as lighting, ventilation, communication signals, and power supplies; and establishing operation and maintenance procedures.

When there is a body of water a type of transport must cross, many factors are considered when determining whether a tunnel or a bridge should be built to provide a transportation solution. While tunnels are more costly than bridges, factors such as navigation for ships, land footprint, and congestion may make tunnels more practical solutions. With tunnels, developers can also avoid tides, weather, and shipping during construction and not be restricted in weight capacities.

Tunnels are the most expensive form of transportation construction and rely heavily on government funds. In addition to managing the overall project, civil engineers must consider the economic factors and politics that go into the decision to build a tunnel. The project duration, number of workers, materials needed, and the amount and type of land that must be excavated must be decided upon in the early planning stages. To swiftly bypass any political pushback, there must be an apparent need for a tunnel. In some cases, increasing taxes may be necessary to raise funds for certain projects and this often results in pushback from the community it impacts.

Geographical factors play a large role in determining the length of a project. Such factors, called "stand-up time," refer to the semisoft earth materials around the tunnel and how long they can safely stand on their own during the dig. Clay, silt, sand, gravel, and mud all have different stand-up times and they are influenced by factors around them, such as groundwater and fault lines. Stand-up time for hard rock is significantly longer, often by years, than soft materials, but, if stand-up times are not

A tunnel under construction in Sweden shows one of two planned concrete layers partially applied on top of a plastic lining intended to prevent water from entering the tunnel.

carefully considered, there is a risk of the ground caving in.

When creating a tunnel through hard rock, workers typically blast the rock or perform a technique known as fire-setting, in which the ground is heated with fire and then immediately cooled with water. Tunnel-boring machines (TBMs) are used to create tunnels in soft materials. This equipment is expensive, ranging into several millions of dollars, but it also provides support to surrounding rock. Other tunnels use a construction method referred to as the cut-and-cover method, which requires placing a tube in a trench and covering it with materials to keep it stationary. The tunnel is then covered with filler materials and excess water is pumped out.

Preservation

The long planning and excavation processes that go into tunnel building are only the beginning of the planning journey. Engineering a smart business model and strategy to preserve these tunnels from age and decay is essential. By in large, tunnels have proved their ability to stand the test of time, although many show signs of aging. The U.S. Federal Transit

Administration (FTA) released a report stating that 28 percent of transit underground structures are in substandard or poor condition.

Ongoing maintenance is needed to prevent expensive overhauls down the road.

The FHWA and FTA together developed a tunnel management system in 2002 that was intended to extend tunnel service life and reduce operating expenses. Many tunnel owners had such policies in place, but prior to this plan there were no national guidelines. In addition, the DOT emphasizes that whether the tunnel is intended for highway or transit purposes, a similar tunnel management system must be in place.

Perfecting the Field

There is a growing team of engineers who belong to the Virtual Team on Road Tunnels (VTRT). This group, created through the FHWA, was developed to expand a network of engineers well versed in the intricate planning of tunnels and to promote road tunnel engineering principles, technology, and maintenance practices.

Goals of this group include forming a national team of road tunnel experts, developing and maintaining a Web site to include a database of ongoing tunnel projects and related publications, and promoting the development of tunnel knowledge. VTRT is in existence to serve the offices of FHWA, state highway agencies, and local governments in their planning stages. Although tunnel development improved dramatically throughout the 19th century and notably in the years since the turn of the century, the process of building tunnels remains so complex that its progress has been severely underdeveloped in comparison to traditional transportation models.

Unique Safety Considerations

Even with the best planning, setbacks can occur when building tunnels. Engineers often encounter unexpected obstacles such as weak soil beds and zones, fault lines, groundwater, water pressure issues, excessive heat, and toxic gas. Gas, carbon monoxide, and smoke production from fires in tunnels are serious dangers when construction is occurring.

Tunnels built for cars must be equipped with ventilation devices to provide air flow should someone be trapped in the tunnel. In some cases, airtight compartments are built in for trapped personnel. Video surveillance and monitors are also frequently

used for vehicle tunnels to monitor traffic and safety conditions. Tunnels with heavy traffic may have their own operational staff.

Improved technology can account for the progress made in tunneling in the last several decades. Tunnels are expanding in size and the time it takes to create them is decreasing. Advanced imaging technology can be used to effectively evaluate the ground surrounding the location. In addition, machinery used to cut through geological materials is improving through greater capacity to cut through heavier rock and a wider range of materials to improve efficiency.

opportunities. The *Highway Capacity Manual* (HCM) developed by the Federal Highway Administration (FHWA) presents the concepts and methods for assessing capacity of different classes of roads and intersections. These are based on various traffic, road/intersection geometry, travel modes, and environmental characteristics. While the HCM can provide an indication of quality of traffic flow, flexibility in design of facilities is important to minimize unnecessarily costly capacity additions. There are many innovative solutions to maintain the capacity and utilize any unused and underused capacity. These include managed lanes, active traffic management, and pricing.

What Is Capacity and Why Is It Important?

Highway or road capacity is the maximum number of vehicles that can reasonably be expected to cross a point on a roadway during a given time period under prevailing traffic conditions and controls such as signals. It is measured in vehicles per hour per lane (vphpl). In the case of intersections, the capacity is measured as a function of delay experienced by a vehicle while crossing the intersection. Capacity can also be measured as level of service (LOS), which describes traffic conditions in terms of speed, travel time, capacity for accommodating more traffic, and so on. While "basic capacity" is the maximum volume that can pass through ideal conditions, "possible capacity" is the same in prevailing conditions that are more restricted. Many factors affect highway capacity, including lane width, shoulder width, road geometry, amount of mode mix, existence of intersections and traffic lights, weather, and presence of parking, pedestrians, and transit.

The road system is key for mobility as well as economic, social, and cultural opportunities. Road systems that function well with reasonable capacity to accommodate future growth in traffic support economic growth. This is especially true for higher classes of roads such as highways and arterials. As the traffic approaches the capacity of the road, we experience traffic congestion. Traffic congestion affects us not only in terms of delays but also in terms of lost work hours, emissions, public health, safety, and negative environmental impacts. Therefore, maintaining the capacity is considered an important aspect of transportation planning.

There are many ways to maintain the level of service. One of the most used methods is to increase

Highway/Road Capacity

Highway or road capacity is the ability of a road or intersection to accommodate traffic. It is important to maintain a certain level of capacity to support mobility as well as economic, social, and cultural

the capacity to keep up with the demand by adding more roads or widening existing roads. However, in recent years, this has been considered costly and physically nearly impossible. Other methods include managing the traffic demand by having compact and mixed land use development as well as encouraging transit and nonmotorized travel such as biking and walking. Managing the traffic on highways with the use of intelligent transportation system (ITS) tools as well as financial constraints such as tolling has seen increased interest. In order to plan, design, and operate road facilities and intersections, it is critical to understand the maximum capacity and current capacity of facilities.

Highway/Road Classification

The highways and roads in the United States are divided into different functional classes. Functional

classification is the process by which streets and highways are grouped into classes, or systems, according to the mobility and access characteristics they intend to serve. The FHWA divides roads into urban and rural, based on census designation of urban and rural areas. These are further divided into arterials, collectors, and local streets. Arterials include interstate highways, freeways, and other highways. They connect, as directly as practicable, the nation's principal urbanized areas, cities, and industrial centers.

Within urban areas, arterials are divided into principal arterials and minor arterials. These roadway categories vary based on the roadway's relationship to mobility and land access. Here, mobility is defined as the ease of movement between points, whereas land access is defined as the access to specific property. Arterials emphasize a high

Looking at a typical two-lane road in New Delhi through a vehicle windshield shows the need for infrastructure improvement. Developing nations around the world are quickly outgrowing existing road capacity, impeding both the economy and the environment. In Mumbai alone, between 1991 and 2005, passenger vehicles increased by 420 percent and taxicabs by 125 percent.

level of mobility for through movement, whereas local streets emphasize the land access function. Collectors offer the middle path—relatively equal importance to mobility and land access. There are overlaps of function and mobility characteristics between different categories. All functional classes are expected to perform within a desirable range of capacity conditions. In order to understand the performance of an existing road or to design a new facility, it is important to develop methods to calculate capacity of the facility.

Highway Capacity Manual and Other Tools

In the United States, the Transportation Research Board (TRB) publishes the *Highway Capacity Manual*, which contains concepts, guidelines, and computational details for calculating capacity and quality of service for road segments and intersections. These calculations take the number of vehicles, road/intersection geometry, traffic controls, on-street parking, transit, pedestrians, and bicycles into consideration. The first HCM was published in 1950 and attempted to quantify the concept of capacity as a response to the rapid expansion of the U.S. roadway system after World War II.

The level of service concept and transit was introduced in the 1965 version (HCM2), and the 1985 version (HCM3) added pedestrians and bicycles into the fold. The 2000 version (HCM4) refined the methodologies using the latest research available and expanded its depth. The 2010 version (HCM5) made substantial revisions to and reorganized the materials. The HCM5 describes methodologies for noise, air quality, economic, and multimodal planning analyses.

The HCM allows for analysis of capacity on points (for example, intersections), segments (for example, road length between intersections), facilities (an aggregation of points and segments), corridors (parallel freeways and arterials), and areas and systems. It takes into consideration all modes, including automobile (passenger cars, trucks, buses, recreational vehicles, and motorcycles), transit, pedestrians, and bicycles. Measures can be calculated for both uninterrupted-flow facilities (access-controlled highways) and interrupted-flow facilities (where signals and stop signs interrupt the traffic flow).

The HCM uses level of service as the measure of capacity and divides traffic movement on roads and intersections into six categories: A being the

best and F the worst. The HCM calculations present vehicular delay in seconds, a ratio of volume to capacity (v/c ratio), and number of vehicles or length of a queue. The delay is then converted into levels of service. LOS A represents a free-flow operation: vehicles are almost completely unimpeded in their ability to maneuver within the traffic flow and travel at or above speed limit. LOS B also represents a reasonably free-flow operation: the ability to maneuver within the traffic flow is slightly restricted but traffic can still travel at speed limit. LOS C represents a stable traffic flow with speeds near or at free-flow speeds of the highway/road: the ability to maneuver within the traffic flow is noticeably restricted. LOS D represents speeds that begin to decline with increased density and approaching unstable flow: the ability to maneuver within the traffic flow is noticeably restricted here, too, with speeds dropping below the limits. LOS E represents operations at its capacity: vehicles are closely spaced within the traffic stream and there are virtually no usable gaps to maneuver. Since it is already an unstable flow, any incidents could severely disrupt the flow. LOS F represents a breakdown of traffic flow: there will be queues forming behind the point of breakdown.

Similar LOS categories are used for intersections as well, with LOS A being the best and LOS F the worst. LOS A is assigned when there is a less than or equal to 10-second delay, while LOS F is assigned when there is more than or equal to 80-second delay for signalized intersections and more than or equal to a 50-second delay for unsignalized intersections. Later versions of the HCM also included analysis of roundabouts, as there had been an increase in the use of roundabouts as an intersection traffic control in the United States.

There are tools other than the HCM for measuring capacity. Sketch-planning tools produce general order-of-magnitude estimates of travel demand and system performance. Microscopic simulation models simulate movement of individual vehicles based on deterministic relationships of flow, speed, and density of traffic. Hybrid models employ both macroscopic and microscopic models to analyze very large networks. The choice of model depends on the objective, geography, facility, traffic conditions, and other factors of analysis, model capabilities, data availability, as well as user interface and ease of use.

Need for Flexibility

Even with all these sophisticated tools for measuring capacity, caution is required to make final decisions. There is variability in traffic conditions from place to place and in different environmental and social conditions. These changes can make significant differences in what is accepted as a good quality travel experience. It is important to understand that the LOS and other capacity measures are only indicators, not absolute values to be followed. The design or reconfiguration of roadways and intersections should also consider other aspects, such as quality of life, pedestrian and bicycle comfort, aesthetics, and environment, among others.

Potential future traffic demand is calculated using sophisticated forecasting models. However, due to the variability of factors such as economic conditions, changes in vehicular and traffic control technology, travel mode preferences, and fuel price, the travel patterns could change in short time periods. This could easily translate into wrong forecast numbers. If designers consider LOS as absolute criteria to be met in road design, any increase shown by models will need to be met to sustain capacity. This could result in costly physical expansion such as extra lanes on segments or turn lanes at intersections. Such expansion could also mean degrading environmental features. Therefore, any capacity calculations for future scenarios must consider other qualitative aspects as well as be flexible.

Innovative Solutions for Increasing Capacity

There are many new solutions being explored and implemented to increase capacity without getting into costly physical expansion of roads. These solutions are mostly based on operational improvements. Some of the most common solutions are managed lanes, active traffic management, shoulder use, and signal coordination. Managed lane is an operational practice utilized to address congestion and maintain capacity by controlling traffic movement on the highway. The FHWA defines managed lanes as “highway facilities or a set of lanes where operational strategies are proactively implemented and managed in response to the changing conditions.”

The managed lane concept regulates demand, separates traffic streams to reduce turbulence, and utilizes available and unused capacity. Typically, this is a freeway-within-a-freeway where a set of lanes

within the freeway cross-section is separated from the general-purpose lanes. The facility incorporates a high degree of operational flexibility so that over time, operations can be actively managed to respond to growth and changing needs. The operation of and demand on the facility is managed to achieve an optimal condition, such as free-flow speeds. The management strategies include pricing (static or variable), vehicle eligibility (for example, minimum occupancy), and access control (for example, access for all vehicles on certain segments).

Active traffic management strategies can be considered as extensions of the managed lane concept. It could change the toll price based on the demand and available capacity to maintain a certain level of service. It could also do a similar treatment for occupancy limitations or access. However, for this strategy to be successful, advanced technologies should be used and multiple agencies should coordinate their activities smoothly.

Other active traffic management strategies include variable speed limits, hard shoulder running, and ramp metering. The variable speed limit strategy allows officials to adjust the speed limit according to weather, traffic conditions, and construction. Drivers could be informed of these changes through use of variable message signs that display allowed speed on different lanes on different stretches of the highway. Other advanced traveler information systems (ATIS) also could be employed. Hard shoulder running allows for use of shoulders as auxiliary lanes during extremely congested travel conditions.

Such shoulder running can also be activated for incident management. A variation of the same concept is to allow transit buses to use the shoulder to move ahead of auto traffic without getting caught in the congestion. Ramp metering is aimed at reducing the volume of traffic entering the highway. Traffic signals stop the traffic on ramps that are entering into the highway. The stored traffic will then be allowed to enter the highway during gaps in mainline traffic. The traffic on the mainline as well as on the ramp is detected using sensors and used in algorithms to calculate the release rate and time. Traffic signal coordination can improve the capacity on urban arterials and collectors. Signals are usually stand-alone and look at traffic entering the intersection from their respective approaches only. However, signal controllers for adjacent intersections

could be coordinated using technology to allow smoother flow of traffic along a corridor. Such innovative methods contribute to better management of traffic and utilize maximum possible capacity.

Highways, Rural and Low-Volume

While definitions vary, rural land occupies roughly 83 percent of the United States. For the purposes of highway classification and planning, the U.S. Department of Transportation (USDOT) defines rural to be a nonmetropolitan area outside the limits of any incorporated or unincorporated city, town, or village.

Rural and low-volume highway planning and policy is decided in a manner that benefits the rural communities these roads impact. In 1999, the USDOT announced the Rural Transportation Initiative to allow these communities to share in the economic and social benefits that many USDOT programs provide, including safety and infrastructure. The initiative gives those in rural America a chance to participate in the planning that shapes their transportation systems.

Characteristics of Rural Highways

Rural roadways are divided into three categories: basic rural, developed rural, and urban boundary rural. Basic rural traditionally does not have more than 5,000 residents near the city center and upgrading roads or access to public transportation is costly. Developed rural includes regions that do have populations reaching over 5,000, yet despite the apparent need in many areas, funding is still difficult to come by to improve road conditions. Urban boundary rural regions neighbor metropolitan, populated areas and the travel conditions vary greatly.

The population of rural communities has continued to dwindle in the United States as people move out of rural communities to urban areas with stronger economic prospects and employment opportunities. Likewise, services such as local stores have disappeared or moved from mid-sized communities to larger shopping centers. Because of the declining population, the Federal Highway Administration believes rural communities are generally supportive of transportation improvement projects to promote economic growth and development in the rural region. Some areas, however, are not supportive of such projects because they do not want spillover from neighboring urban areas and wish to leave the character of the rural region intact.

Safety Concerns

Low-volume roads and highways offer unique challenges, including long distances between population centers, steep grades, mountain passes, and extreme weather conditions. Low-volume highways consequently have long distances between population centers, deficient roads in many areas, and high vehicle speeds. For this reason, the fatality rate of rural highways is twice the average for urban roads. It often takes a longer time for emergency response personnel to arrive to an accident scene due to these long distances.

Economic Planning

Rural populations are widely dispersed, making their planning all the more important. Highway network planning not only connects rural citizens to jobs, health care, food, and family but also brings consumers, such as tourists, to the region to support the local economy. The vast majority of all goods nationwide are shipped into and out of states by truck because of the flexibility and door-to-door

A rural highway runs through Marshall County, Indiana, in 2005. One problem facing rural highway planners in some areas, such as near the U.S. borders with Canada and Mexico, is increased truck use of roads that were not built to handle such traffic. In some of these areas, the volume of truck traffic using rural road networks has grown by as much as 80 percent since 1994.

service provided by trucks. For this reason, the size of the trucking industry and reliance on highways remains large in the United States.

Rural economies were often based on occupations such as farming, mining, and forestry. These industries play a major role in highway planning, as the highway network is largely how products are exported. The agricultural sector is changing in many respects, as well. For instance, livestock production is now focused on higher productivity and this results in increased truck traffic in locations that previously never faced this problem. In addition to transporting goods, tourism and recreation create new travel demands, particularly among rural communities. Attractions such as state parks, lakes, waterfalls, ski lodges, mountains, and rivers create high traffic, depending on the season.

Lack of Funding

Although the initial building of interstate highway infrastructure is typically provided by the federal

and state governments, the maintenance of such highways is the responsibility of the local municipalities. Funding for low-volume road maintenance and preservation is difficult to provide, causing many of these highways to deteriorate. The local governments supporting these highways simply do not have the funding or the means to generate the necessary tax revenue. Forty percent of rural roads in America are inadequate to drive on.

The issue of funding also prevents the expansion of rural highways. Despite relatively smaller and less dense populations, increases in traffic often outpace the capacity of local highways. The cost of expansion, however, is high, and these projects very often get lost when in competition with highways of state and national significance.

Examples of this can be found along the Canadian and Mexican borders, where truck traffic in rural areas has greatly increased—by as much as 80 percent in some areas since 1994. However, it remains difficult to come by the funding to expand these highways.

Planning for Low-Volume Highways

As with planning of any highway infrastructure, planners of rural highways must consider the current state of the roadways, what the desired result is, and how that can be achieved. Planning for the multimodal system means taking into account not only the needs of local agencies but also state and national goals. Plans must be coordinated and comparable with different levels of government in addition to land use plans and transportation plans. Most local governments have land use policies, although these may lack a transportation component, making it difficult to cross-reference in the planning stages. Finally, having highly qualified personnel on the job is key. State departments of transportation (DOTs) do not always have staff who are specially trained or have highly technical expertise in areas such as forecasts, pavement condition analysis, and traffic and accident statistics.

Planning approaches can be locally led, state led, federally led, or take a mixed approach. In all instances, the needs of each government entity must be evaluated. Responsibilities of the state DOT in the planning process include addressing needs of both state and local communities.

In basic rural communities, planning needs are primarily focused on preserving and maintaining the current system rather than on expanding and building new infrastructure. For developed rural areas, there is an increased focus on forecasting and on finding ways to fund improvements in sporadic areas of high traffic growth. Planning needs for urban boundary rural regions can be described as having a need for growth management. In these regions, a balance between economic development and preservation must be struck.

Highways, Social and Economic Impacts of

The Interstate Highway Act was passed in 1956 to advance the development of new highway infrastructure, which has served an important function in transforming human society and affecting population dynamics. The social and economic impact of highway systems is vast and complex. This article summarizes the impact (positive and negative) of highway systems; the theoretical explanation of those impacts on economic growth, population, and employment change; and altered sociodemographic structures, as well as the temporal and spatial variations of the impact.

Highway systems have both positive and negative impacts. The positive impact includes induced economic growth and development, decreased traffic congestion, increased travel safety, and more efficient use of existing roads. These positive consequences are often cited by governmental decision makers when they argue for the construction of highways.

In the opposition, environmentalists and local communities have often protested ardently against highway construction based on the potential negative effects of highway construction, for example, disparities in highway access, spatial mismatch, less frequent family interactions, and transportation-related stress.

The Roles of Highway Infrastructure

The complex impact of highways can be better understood by looking at the societal and economic roles of these highways. As the literature on the subject has been published in several disciplines

(for example, geography, sociology, economics, and urban and regional planning), theoretical and empirical approaches to describe the social and economic impacts of highways are diverse and represent many perspectives. Such diversity in the literature also leads to a variety of definitions and explanations regarding the function of highways in society and economy. The three regional economic theories that explain the impact of highways most soundly are neoclassical growth theory, growth pole theory, and location theory.

According to neoclassical growth theory, highway infrastructure provides input into the production process and thus augments the productivity of other inputs, such as labor, but also attracts workers as a household amenity factor. The explanation and prediction of metropolitan development after the highway network is built, according to neoclassical growth theory, is insightful.

Growth pole theory explains investments in highway construction as a catalyst for change, though it concedes clearly that simply improving a highway is neither a necessary nor a sufficient factor for bringing about growth in its surrounding areas because economic decline can also be a result (that is, backwash). Growth pole theory lends itself to forecasting economic growth for decision makers, because it can pinpoint how limited resources should be allocated in a region in order to ensure economic growth and development.

In location theory, highway infrastructure aids the flow of raw materials, capital, finished goods, consumers, and ideas between central locations and their surrounding neighborhoods. The strength of location theory lies in the interpretation of the geographic distributions of human settlements; for example, central place theory, which is a specialized branch of location theory, explains the polycentric city model powerfully.

Although scholarly definitions of the particular role of highway infrastructure vary depending on their regional economic theory, they are in agreement that highways significantly impact regional economic growth and development. Each interpretation of the role of highway infrastructure has merits.

Economic Growth or Decline

Empirical studies demonstrate that interstate highways have significant influence on economic growth and development as they boost travel and

improve accessibility. Most of these studies either measure highway impact on economic activity at a macro level (for example, national or state level) typically based on growth theory, or investigate the economic impact of infrastructure investment at a local level with the help of firm location theory. Both of the two directions of study have resulted in distinct and sometimes contradictory conclusions.

For example, some studies attribute significant augmentations of output, economic growth, and wage structures to public infrastructure, whereas other studies found other factors to be far more important than public infrastructure for explaining economic growth. Establishing the actual impacts of interstate highways on economic growth and development is a complex task, first because the evidence can be interpreted in vastly different ways, and second because so many factors besides highways impact economic growth and development.

Population and Employment Change

Highways bring about changes related to population and employment in at least four ways. First, residential housing in rights-of-way must often be removed, triggering a direct decline in population size in local communities. Second, their impact on economic growth or decline triggers further change for population and employment. Third, improved highways provide access to additional employment opportunities within reasonable distance for a commuter or shorten existing commutes, saving employees time and/or money. Fourth, new highways create new employment opportunities, particularly in occupations of service such as automotive service stations, lodging accommodations, retail strip malls, and eating establishments.

Altered Sociodemographic Structures

Highways also influence sociodemographic structures significantly through at least four ways. First, a highway's impact on economic development can further lead to augmented residents' socioeconomic status and give them access to a wider variety of employment opportunities. Second, highways may change how industrial and occupational distributions are spread throughout local communities, affecting the existing social structure. Third, as the improvement of highways provides access

to more and different social institutions (such as schools and hospitals) and cultural opportunities, housing prices are influenced by the associated accessibility premium.

Moreover, highways could lead to segregations, by race and/or income. In environmental justice and social inequality literature, highways are interpreted as unfavorable infrastructure as they bring environmental pollution such as noise, dirt, and fumes to the right-of-way and nearby communities. In urban areas, highways also create “crime” spaces that people avoid. Thus, the reduced livability lowers the land values and real estate values of immediate neighbors, often causing so-called white flight. Resulting vacancies are more likely to be filled by minorities.

In addition, studies have shown that the presence of disproportional minorities increases the likelihood that unfavorable facilities may be built in an area and that environmental injustice is a consequence of discriminatory siting practice. The argument surrounding unfair siting selection is parallel to some historical ones regarding highway construction used as a tool to separate minority communities from white communities in the first half of the 20th century.

Variation of the Impact by Stages of Highway Construction

Experts in demography and regional economics often claim that the relationship between highways and economic growth resembles the question about the chicken and the egg: a relationship of mutual influence with feedback effects. While a highway of higher quality stimulates travel and economic growth, the resulting travel and economic growth lead to the demand for even better highway access.

Since the development of new highways is a process of several (if not many) years before the public can fully take advantage of it, the question arises as to how the economic impact varies in different stages of highway construction, namely, in the preconstruction stage, the construction stage, and the postconstruction stage. Most research tends to conclude that economic and population growth are the causes for highway construction in the preconstruction period.

During actual construction, however, the construction is the cause for economic and population

change because decisions have already been made and the highway construction is in process. Once construction is finished, highways further advance economic and population growth.

Spatial Variation of the Impacts

The social and economic impacts of interstate highways vary in rural, suburban, and urban areas. In rural areas, highways substantially influence living conditions; accordingly, rural development efforts often rely heavily on highway infrastructure as a major tool. Areas that were previously considered too distant from a metropolis can be within a reasonable commuting range thanks to an improved highway.

This in turn can increase rural population through added employment opportunities in or near the surrounding rural areas. Most studies on nonmetropolitan counties have revealed positive effects of interstate highways on economic and population change as they attract migrants and foster employment growth.

In suburbs, the impact of interstate highway investment is also mostly positive on general development and population growth. Suburbs in metropolitan areas grow because suburban life offers important benefits over central city life. For example, the central city may struggle with congestion, spatial economic squeeze, and residential deterioration. Consequently, the availability of modern highways hastens a tendency to move outward to fringe areas surrounding the city. Though the new highways may not directly cause this tendency, they offer a better connection between the suburb and the economic center of an urban area. Improved highways shorten commuting times to and from work.

In urban areas, the relationship between interstate highways and economic and population growth is of a more complex nature than in rural areas. The net effects of highways cannot be easily predicted there. They may aid or prevent development, always depending on many other factors, the net effects of spread and backwash, and the scale effect. For example, among immediate neighborhoods, interstate highways are considered a disamenity, while neighborhoods just a few blocks farther will see them as an advantage.

In summary, the social and economic impacts of highway systems are complex. It is suggested

readers consider a variety of perspectives of highway systems as discussed above.

Historic Transportation Facilities

One of America's earliest transportation images is Paul Revere riding his horse to warn patriots that the British were coming, while 21st-century transportation imagery boasts superhighways, supersonic jets, and the probabilities of commercial space travel. Although the nation has progressed light-years from the era of horses, canals, steam engines, Model Ts, and monoplanes, artifacts from the transportation past still dot the landscape, some recycled and some repurposed. Barges still ply a few of the old canal networks and pioneer roadways such as the Lincoln Highway and Route 66 have been incorporated into existing highway systems. Abandoned railroad beds have been repurposed into recreational trails. Rockets leave vapor trails in the sky as they speed toward the stratosphere, while airplanes belonging to Wilbur and Orville Wright and Charles Lindbergh are displayed in the National Air and Space Museum.

Canals

Canals have played an important part in American transportation, and thousands of them still operate as part of the U.S. maritime grid. Built between 1817 and 1825, the Erie Canal runs about 363 miles from the Hudson River in Albany, New York, to Lake Erie at Buffalo, New York. Containing 36 locks, the Erie Canal provides a navigable water route from the Atlantic Ocean to the Great Lakes.

The Erie Canal was the first transportation system between New York City and the Great Lakes that did not require portage; using the waterway instead of wagons to move freight cut transport

costs by about 95 percent. The Erie Canal stimulated a population explosion in western New York State, opened midwestern regions to settlement, and elevated New York City to the chief port in the United States. Between 1834 and 1862, the Erie Canal was enlarged, but in 1918, the larger New York State Barge Canal replaced it. Today, the Erie Canal is part of the New York State Canal System.

In 2000 the U.S. Congress designated the Erie Canalway a National Heritage Corridor to recognize its national significance and its place as one of the most important civil engineering and construction accomplishments in North America. Commercial traffic increased on the Erie Canal in 2008, but recreational boats still provide most of its traffic load.

In 1823, the state of Illinois created a Canal Commission to oversee the design and construction of the Illinois and Michigan Canal, finished in 1848 at a cost of \$6.5 million dollars. The Illinois and Michigan Canal furnished the first complete water route from the East Coast to the Gulf of Mexico by connecting Lake Michigan to the Mississippi River through the Illinois River. The canal begins at the Chicago River's south branch at Bridgeport and extends 96 miles to the Illinois River at LaSalle. Mules and horses toiling along the tow paths pulled the barges that composed the canal's commercial traffic.

With the completion of the Illinois Waterway in 1933, the Illinois and Michigan Canal was closed to navigation but was soon developed for recreation. Visitors can follow the Illinois and Michigan Canal State Trail along the old tow path from Rockdale to LaSalle along 61.5 miles of scenic views of the Des Plaines and Illinois Rivers. Numerous state parks, historical sites, and abundant wildlife as well as distinctive landscapes line its banks. Interpretive programs and information centers are located at key places along the trail.

Railroads

As the major corporations of the 19th century, railroads brought sweeping social, economic, and political change to the United States. They sparked a building boom of bridges, depots, and towns and allowed ruthless rail magnates and magnificent steam locomotives to rule the country.

Railroad names like the Baltimore & Ohio, the South Carolina Canal and Rail Road Company, and the Mohawk & Hudson Railroad became familiar to Americans. One of the greatest technological

advances of the time occurred at Promontory Summit in the Utah Territory, when the Central Pacific Railroad, starting in San Francisco, California, and the Union Pacific, starting in Omaha, Nebraska, met there on May 10, 1869, linking the eastern and western coasts with slender, steel rails. By the 1930s, the railroad companies had built an efficient transportation network that crisscrossed the country, but the advent of cars, buses, trucks, and aircraft provided cutthroat and ultimately decimating competition. The amount of track in the United States peaked at 254,261 miles in 1916, but by 2007 it had declined to 140,695 miles.

Steam Locomotives

Steam locomotives evolved along with railroads. Originally used to haul coal and other materials, railroads quickly adapted steam engines to haul passenger trains. Steam engines became larger, more powerful, and faster, their two-cylinder

A marker stands at the site of the western terminus of the Lincoln Highway in San Francisco's Lincoln Park. A street sign also marks the highway's starting point in Times Square in New York.

design expanding to four cylinders. Companies added gears to locomotives that operated on industrial, mining, quarry, or logging railways. From the 1930s to the 1950s, diesel and electric trains gradually replaced steam locomotives.

In the 21st century, steam locomotives are used for historical, educational, or entertainment functions. Railroad museums feature exhibits built around the history of steam engines, including the preserved and operational steam locomotives themselves. Many museums and railroad societies offer steam engine trips, including Steam Town in Scranton, Pennsylvania, and the Pacific Southwest Railway Museum in Campo, California.

Rails-to-Trails

A 1960s rails-to-trails movement to convert abandoned or unused rail corridors has grown into a social and ecological network. Once unused tracks disappeared, people started walking the old grades, socializing and discovering the countryside. In the winter, they skied or snowshoed the corridor. Half a century later, 15,000 miles of rail trails and over 100 million users a year contribute to the national trails system.

The 237-mile Katy Trail stretches across most of Missouri, with over half of it following the path of Lewis and Clark up the Missouri River's towering bluffs. It is America's longest "rail to trail" route, following the former Missouri Kansas Texas rail line. After it leaves the Missouri River, the trail winds through farmland and small towns, providing ideal terrain for hiking, running, cycling, and horseback riding on the Tebbetts-Portland section.

Moving Down the Highway

Henry Ford did not create automobile technology, but he did perfect and popularize it by introducing the assembly line in automobile manufacturing and offering a \$5-a-day wage that he hoped would increase worker productivity and encourage those workers to use part of their earnings to buy a new car. These innovations helped make the automobile accessible to the American public. By the end of the 1920s the number of registered drivers had reached 23 million, despite the fact that they could only order Ford's Model T in black at a cost of \$490. In 2007 the U.S. Department of Transportation estimated that there were 254.4 million registered passenger vehicles in the United States.

When Henry Ford commercialized the automobile in the early 20th century, the United States already possessed a network of auto trails often marked and maintained by organizations of private citizens. The National Road, the Lincoln Highway, the Dixie Highway, and Route 66 are just a few of America's vintage roads that connect the present with the past.

In 1806 Congress passed an act creating the National Road and President Thomas Jefferson signed the act into law, allowing for a road connecting the Atlantic Ocean and the Ohio River. Historically known by various names, including the Cumberland Road, National Pike, and Western Pike, the National Road eventually ran approximately 800 miles from Baltimore, Maryland, through Pennsylvania, West Virginia, Ohio, and Indiana, officially ending at the old statehouse in Vandalia, Illinois. With the advent of the Federal Highway System in the late 1920s, the government folded the National Road into its design for U.S. Route 40. In the era of the transcontinental and interstate highway systems much of Route 40 disappeared into state highway systems, with Interstate Highways 70 and 68 paralleling the National Road, although a careful scrutiny of the roadway still reveals traces of earlier paths.

The Lincoln Highway Association maintains the Lincoln Highway, which stretches from Times Square in New York City to Lincoln Park in San Francisco, and at times in its history passed through 14 states, 128 counties, and more than 700 cities, towns, and villages. Formally dedicated October 31, 1913, the Lincoln Highway is a national memorial to President Abraham Lincoln and one of the first automobile roads across America, bringing economic prosperity to the places it touched. It wends its way through historic places, several national parks, and a few major cities.

Although it has been reconfigured over its 100-year life span and parts of it have been incorporated into state and interstate highway systems, much of it as U.S. Route 30, remnants of the Lincoln Highway still exist across America. In 1992, the Lincoln Highway Association reformed with the mission of identifying, preserving, and improving access to the Lincoln Highway. The Lincoln Highway is on the National Register of Historic Places, and motorists from all over the world drove vintage automobiles along it to celebrate its centennial in June 2013.

The Lincoln Highway inspired the slightly younger Dixie Highway. In 1914, the Dixie Highway Association planned for this road to be part of the National Auto Trail system connecting the U.S. Midwest with the southern United States. Constructed and expanded from 1915 to 1927, the Dixie Highway evolved into a network of connected paved roads instead of a single highway. In 1927, the Dixie Highway Association disbanded and the Dixie Highway became part of the U.S. Route system, with some part of it converted to state roads. Several states continued to identify the “Dixie” or “Old Dixie” Highway.

By the late 1920s, a system of numbered U.S. highways replaced the auto trails, and Congress passed the Federal Highway Act of 1921 to further establish a network of roads. U.S. Route 66, affectionately known as the “Main Street of America,” was one of the original numbered highways. Established on November 11, 1926, Route 66 originally ran 2,448 miles from Chicago through Missouri, Kansas, Oklahoma, Texas, New Mexico, and Arizona to its destination in Los Angeles, California.

Communities along Route 66 became prosperous as the highway increased in popularity and Route 66 went through many improvements and realignments until June 27, 1985, when the U.S. government removed it from the U.S. highway system after replacing it with newer roadways in the Interstate Highway System. The U.S. Department of Transportation designated Route 66 a National Scenic Byway, renaming it Historic Route 66, and several states have incorporated bypassed sections of the old highway into their state road networks, calling it State Route 66. People have restored gas stations, motels, and other businesses along the old Route 66, and every year—maps in hand to make the right connections—people from all over the United States and the world motor the original Route 66.

Airplanes and Spaceships

On December 17, 1903, at Kitty Hawk, North Carolina, Wilbur and Orville Wright flew the first heavier-than-air machine in a controlled, sustained flight with a pilot aboard. Designed and built by the Wright Brothers, who solved the basic problems of mechanical flight (lift, propulsion, and control), the Wright Flyer’s longest flight measured 852 feet and lasted 59 seconds.

World War I aviation technology, Colonel Billy Mitchell, and Charles Lindbergh advanced the

cause of aviation during the 1920s and 1930s. Air power dominated World War II, and technological advances in aviation after World War II ushered in the jet and space ages. The Yankee Air Museum at Willow Run in Belleville, Michigan, houses a Willow Run bomber and other World War II airplanes, and the Smithsonian Institution’s National Air and Space Museum in Washington, D.C., displays the Wright Flyer and Charles Lindbergh’s *Spirit of St. Louis*.

The 21st-century space age features National Aeronautics and Space Administration (NASA) solar system missions, and NASA’s Voyager 1 space probe is speeding 11 billion miles from Earth and will soon explore interstellar space. Back on Earth, companies like California-based Space Exploration Technologies Corporation are researching the parameters of commercial space travel, and the U.S. Astronaut Hall of Fame in Titusville, Florida, displays astronaut Gus Grissom’s MR 4 space suit as a reminder of the price of the transportation revolution.

Hitchhiking

Hitchhiking as a form of transportation involves the solicitation of free rides from passing motor vehicles at the side of a road, normally from strangers (although hitchhiking can occasionally involve other forms of vehicles). Also referred to as thumbing, autostop, trampen, or hitching, hitchhiking is

variously seen as an economic necessity, a means of escape or adventure, a sustainable mode of travel, and a way of overcoming a lack of public transit. To request a lift, it is commonplace for hitchhikers to extend an arm toward the road, with a raised thumb and clenched fist, or to present a sign or placard with the desired destination or route clearly visible to passing vehicles—although this form of signal is most common in Europe and the United States. A journey achieved by hitchhiking often involves more than one ride.

Hitchhiking became popular in the 1920s following the emergence of the automobile. Since the 1970s, however, the practice of hitchhiking has generally seen a decline in popularity as a result of the risks and dangers that have been associated with sharing a car with strangers—both for the hitchhikers and for the motorists who pick up hitchhikers—although there have been calls to revive it as an alternative mobility and more eco-friendly form of transport.

Hitchhiking is often associated with the emergence of social inequalities. For example, in times of economic necessity, such as the Great Depression, hitchhiking was a common form of transportation and a necessity for Americans migrating in search of labor. During this time, picking up a hitchhiker was considered a civic good or duty. Similarly, in Cuba, a shortage of cars as a result of the collapse of the Soviet Union and the U.S. trade embargo made hitchhiking an ordinary cultural practice and requirement. It continues to be encouraged by the Cuban government as a means to address the shortage of transportation and ease pressures on an overcrowded public transit system. Any government vehicle with room for another passenger is required to stop by law (although this only applies if the hitchhiker is a Cuban national).

Safety, Fear, and Security

Much of the decline in hitchhiking has been attributed to its perceived dangers, although there have been efforts to connect its decline to a rise in the provision of affordable public transit—a connection that has largely been discredited. In the United States in particular, high-profile antihitchhiking campaigns in the 1950s by public relations firms, insurance companies, government agents, and sections of the media positioned the hitchhiker as a potential threat to motorists. For instance,

campaigns by the Federal Bureau of Investigation (FBI) encouraged drivers to avoid hitchhikers to ensure their personal safety and protect themselves from potentially violent strangers.

While these campaigns raised questions about the safety of picking up hitchhikers, high-profile cases of attacks on hitchhikers highlighted the danger of hitchhiking not only for motorists but for hitchhikers as well. This was particularly the case for female hitchhikers who were considered to be vulnerable to attacks by male motorists and therefore were targeted by awareness campaigns that aimed to encourage other forms of travel. In some instances, this led to the creation of female-only hitchhiking networks, where women would only travel and hitch with other women as one way of avoiding the perceived threat of unwanted male attention and violence.

Legal Status

Despite fears about the safety and security of hitchhiking, there are few places where hitchhiking is completely outlawed. There are no restrictions in Europe, although the extent to which hitchhiking is considered culturally acceptable varies from country to country. Similarly, in the United States, the acceptance of hitchhiking is dependent on local governments. There are, however, restrictions on where hitchhikers can solicit rides. This includes prohibition on all roads where pedestrians are banned, including motorways, interstates, autobahns, and road shoulders in Australia. However, the degree to which laws are enforced is variable.

As a result of restrictions, hitchhikers tend to occupy gas (petrol) stations, on-ramps, rest areas, service areas, toll stations, or official stops, such as the ones located around university campuses or towns, or on the edge of cities, as is the case in Cuba. Given the variability in acceptability and legislation, online communities of hitchhikers have been established to create hitchhiking maps and to swap tips, advice, experiences, and knowledge of local customs and etiquette, to help travelers locate the best sites to catch a ride and to help avoid fines. There are also many hitchhiking guides and magazines that have been established to promote hitchhiking as a nomadic, sustainable form of transport.

Hitchhiking and Youth

As a mode of transport commonly linked with economic necessity, hitchhiking is often associated

with youth and students. At the height of its popularity, areas surrounding universities and college campuses became common sites for hitching, often as a result of a lack of adequate transportation to and from campuses. In the Netherlands, official hitching spots in university towns are common, although hitching by students has declined since the introduction of free public transport for students. In the United Kingdom (UK), there is still an official hitching post on the campus of Lancaster University, which has become a tourist attraction.

Hitchhiking is also at the heart of a UK university charity fund-raising competition known as Jailbreak, which gives students 36 hours to see how far they can hitchhike without spending any money. The event is described as an adventure that relies on the powers of persuasion and “sweet-talking” to hitch a ride. It often involves hitching rides in motor vehicles, public transport, and airplanes to enable the participants to cover greater distances.

As a choice of travel, it is also considered to be a form of adventure and an expression of resistance, associated with nomadism, disorder, freedom, deviance, and youthful rebellion. This understanding of hitchhiking emerged in 1950s postwar America, when the hitchhiker was stereotypically considered to be part of a counterculture that was antiestablishment, nomadic, and engaged in political activism. Hitchhiking, for instance, was often seen as a way of escaping the suburbs, rejecting middle-class family values, and achieving new mobility outside normal economic trade relations and community attachments. This was a common representation in popular culture at the time.

Recently, attempts to revalorize the sociability of hitchhiking as an alternative mobility culture and form of community have acknowledged a rise in the organization of “hitchhiking gatherings” whereby hitchhikers travel to an organized destination to camp and exchange experiences before hitchhiking back to their origins.

The rise of hitchhiking gatherings highlights the new values that are attributed to the practice of hitchhiking as a form of travel that privileges social exchange, unexpected encounters, and a slower pace of travel.

Carpooling and Sustainable Travel

Questions have been raised about the differences between hitchhiking and carpooling schemes,

which have been growing in popularity as a more environmentally friendly way of traveling. It is generally accepted that carpooling initiatives are more likely to involve commuters and suburban residents, who arrange to share a ride with others and split the costs and burden of driving over a sustained period of time. Hitchhiking is therefore distinguished from carpooling schemes by a lack of both prearrangement or organization (with the exception of hitchhiking gatherings) and the reliance upon strangers (and thus the perception of risk involved). While hitchhiking can support sustainable transport agendas by reducing the number of vehicles on the road, greater emphasis is placed on its links to nomadism, social exchange, and adventure, and as an alternative form of mobility and cultural practice.

There is a lack of policy concerning hitchhiking and the conditions under which it might become a possible solution for transport shortage or sustainability. The lack of policy interest is largely as a result of its presumed associations with risk and insecurity. There have been calls for more regulations and more organized forms of hitchhiking, whereby lifts might be prearranged to reduce the element of uncertainty or where both drivers and hitchhikers might be registered to practice hitchhiking or to provide a ride. The use of Web sites has become a popular means to do this. However, there have been arguments about whether such forms of transportation might still be considered hitchhiking in the strictest sense.

Popular Culture and the Media

Hitchhiking has featured prominently within popular culture and the media, and it is important to reflect on the close relationship between the media and hitchhiking in order to understand the rise and fall of its popularity as a method of travel. Hitchhiking was a prominent theme in John Steinbeck's writing on the Great Depression. Novels like *The Grapes of Wrath* highlighted the necessity of hitchhiking in the search for work. Ida Lupino's *The Hitch Hiker* (1953) features a hitchhiking serial-killer who kills the motorists who offer him a ride. This film, alongside other films noir, was credited with heightening the fear associated with hitchhiking in the 1950s.

Another prominent example is Jack Kerouac's *On the Road* (1957), which follows the adventures of Sal

and Dean as they travel across the United States in search of excitement, adventure, and the exhilaration of the open road. The book depicts the resistance and counterculture associated with hitchhiking as a form of youthful rebellion in the 1950s and 1960s. Autobiographical travel books include Tony Hawks's *Around Ireland With a Fridge* (1998).

Hybrid Automobiles/ Hybrid Electric Vehicles

Hybrid automobiles, or hybrid electric vehicles, are automobiles that use both a traditional fuel-burning internal combustion engine and an electric power train. Electrical power is stored in onboard batteries, which may be charged either by the internal combustion engine or (in the case of plug-in hybrids) by being plugged into a power source to draw electricity off the grid, as full-electric vehicles do. Most of today's hybrids also make use of regenerative braking in order to improve energy efficiency and reduce waste heat. Hybrids in general have better fuel economy than similar conventional vehicles and use smaller internal combustion

engines, without facing some of the disadvantages of full-electric vehicles.

In today's infrastructural landscape, the main disadvantage of an electric car intended for mass production is the need to recharge the automobile's batteries. While this may be possible at home—and even then, apartment dwellers among others may have difficulty recharging at home—it is far more difficult on the road, and except in California, recharging facilities are not common at U.S. gas stations.

Many hybrid cars use a start-stop system, which reduces the amount of time the engine spends idling by automatically shutting off the internal combustion engine when the car is stopped (such as in heavy stop-and-go traffic, in line at drive-throughs, or at traffic lights). Originally introduced for conventional internal combustion engine vehicles in the 1970s amid concerns about volatile gasoline prices, start-stop systems have become more common in hybrid vehicles. In particular, this improves fuel and energy efficiency in city driving, which is typically the least efficient mode of driving. Powered features like onboard radio and climate control are usually designed to run off the electric motor rather than stopping and starting with the engine.

While many drivers have absorbed the idea that every engine start induces wear on the engine, this is really only significantly true of cold starts (when the car has been stopped long enough for the engine to cool down), especially in cold weather. The short stops of a start-stop system do not weather the engine in the same way, as the oil that lubricates it has remained warm.

On the other hand, batteries do wear out faster when a start-stop system is used, especially the absorbent glass mat (AGM) lead acid batteries used by most automobile manufacturers—but even so, replacing a battery thus worn down is a much cheaper proposition.

Mazda in 2011 introduced an improved stop-start system, the i-ELOOP, which determines which piston in the internal combustion engine is in position for the fastest restart of the engine, resulting in a restart time of less than half a second, and which while decelerating into the stop converts kinetic energy to electricity that is stored in a double-layer capacitor that powers the car's electrical system during the stop period.

Some hybrids have been called "electric assist" vehicles, or mild hybrids, because they lack a mode

of propulsion that depends only on electricity, requiring the use of the internal combustion engine for that. The electric motors in mild hybrids are small and replace the starter and alternator of the conventional design, improving the car's efficiency and making a start-stop system possible. Though regenerative braking is often used, it recovers far less energy than in full hybrids, and in general the fuel efficiency gains of a mild hybrid design are, as the name indicates, mild. Honda's Integrated Motor Assist feature is an example of a major manufacturer's mild hybrid design, as is the discontinued hybrid version of the Chevrolet Malibu.

Mild hybrids use motor-generators, power transducers that are also used by many other hybrid designs. Most manufacturers have developed proprietary motor-generators for use in their vehicles, with mild variations on the same fundamental design principles, such as Toyota's Hybrid Synergy Drive. All such drives are electrical generators that can also function as motors. In the case of mild hybrids, their motor power is limited and powered by electricity generated by the internal combustion engine while it is in use.

Regenerative braking is a popular feature in hybrid cars and greatly assists in their energy efficiency and emissions. All braking systems work, by definition, by reducing the kinetic energy of the car's forward motion. Conventional automobile brakes accomplish this by friction. Applying friction increases the amount of necessary force required to turn the wheels, which then slow down much faster than if the car were to simply coast to a stop (slowed by the friction of its contact with the road). Excess energy is converted into waste heat. Regenerative braking instead reclaims as much kinetic energy as possible, diverting it to operate an electric motor in order to generate electricity, which is then stored in the onboard batteries. Conventional brakes are still used as well, however, because regenerative braking does not function well at low speeds, at which point friction braking does the rest of the work. Regenerative brakes also do not work to keep cars from rolling down inclines.

The use of hybrid cars has been encouraged in the United States through various means in order to reduce America's dependence on fossil fuels, America's contributions to greenhouse gas emissions, and the impact of gasoline price volatility on the American economy. A federal income tax credit was

offered from 2005 to 2010, for instance. The American Recovery and Reinvestment Act of 2009 opted to focus on infrastructure improvements rather than consumer incentives, but new legislation has added tax credits for plug-in electric vehicles. Several states (including Arizona, California, Florida, New York, and Virginia) also allow certain hybrid cars to use carpool/HOV lanes with only one passenger, based on the premise that hybrid car usage offers a fuel efficiency benefit comparable to that of carpooling. San Jose, California, formerly offered a free parking permit to hybrid vehicle owners whose cars had been purchased locally, and Los Angeles offers free parking in city-owned parking spaces for all hybrid or fully electric vehicles. Other cities have considered similar initiatives, though the 2008 financial crisis has tabled many such discussions.

Though hybrid designs were developed at the dawn of the 20th century, not until the end of the 1990s were any hybrid cars made widely available. The Toyota Prius and Honda Insight were the first major hybrids available in the United States and remain leading brands today. Though modern hybrids premiered on the Japanese market (and a larger percentage of the Japanese market is made up of hybrids), the United States has become the largest hybrid market in the world, with over 2.5 million hybrids sold by 2013.

Major hybrid vehicles in the 2010s include the Toyota Prius, Honda Insight, Cadillac ELR, and hybrid versions of the Toyota Camry, Ford Fusion, Volkswagen Jetta, and Honda Accord. Major launches have also been scheduled for a Toyota RAV4 hybrid, diesel hybrid Volvos, and hybrid versions of the Toyota Corolla, Hyundai Accent, and Mercedes-Benz E-Class.

Hydrogen Fuel

Like electricity, hydrogen is not an energy resource but an energy carrier, meaning that it stores energy that has been generated by some other means. It can be used as a fuel by means that release the energy it stores, such as through an electrochemical fuel cell or by burning the hydrogen in a combustion engine. When used for combustion, nitrogen oxides form, contributing to smog and acid rain, but this is characteristic of all combustion (in atmospheres with sufficient nitrogen and oxygen) regardless of fuel type. In other respects, hydrogen is a zero-emission fuel. Unlike fossil fuels, it does not rely on a depletable resource.

Pure hydrogen is rarely found, because as the lightest element on Earth, it rises into the atmosphere, but it can be manufactured. There is considerable interest in developing hydrogen as an alternative transportation fuel. However, the manufacture of hydrogen requires more energy than it can later provide as a fuel (a natural limitation of the conservation of energy), and involves environmental impacts the severity of which in the event of large-scale hydrogen production sufficient to significantly reduce the use of fossil fuels is unknown.

Hydrogen's energy density is low by volume but high by weight, given its lightness. It is usually compressed or liquefied for transport, delivery, and fuel use. In the current state of automotive technology, a hydrogen-burning internal combustion engine has a maximum energy efficiency of 38 percent, compared to the 30 percent of a gasoline-burning engine. This efficiency can be further increased with a hybrid hydrogen-electric design

using hydrogen fuel cells, but until there is a technological breakthrough or an increase in demand sufficient to reap the benefits of economies of scale, hydrogen fuel cells will be prohibitively expensive for use in most consumer vehicles, with a wholesale cost higher than the retail cost of many cars. Further, the purity requirements of hydrogen fuel cells are far more stringent than that of hydrogen-burning engines, which makes their operating costs more expensive.

However, a Japanese start-up company, Aquafairy, announced in 2013 plans to introduce affordable hydrogen fuel cells in 2014, based on a solid form of hydrogen. At the time of the announcement, its working prototypes were insufficient for powering a vehicle, better-suited to powering appliances during power outages or while camping, but vehicle-sized fuel cells were in the planning stages.

Hydrogen Production

Hydrogen production is a \$100 billion industry, but most of the hydrogen produced is not for fuel but rather to be consumed by other industrial-scale chemical processes, such as the production of ammonia or methanol. About half of U.S. hydrogen production is consumed by oil refining (which is one reason natural gas producers have had such an interest in large-scale hydrogen production). Most of the rest is used in the production of ammonia for fertilizer.

In the 2010s, hydrogen production capacity in the United States is about 3000 million cubic feet per day. Multiple technologies make hydrogen production possible, but about 95 percent of American hydrogen production comes from natural gas reforming. Natural gas reforming takes advantage of existing natural gas delivery infrastructure and uses some of the methane (CH_4) found in natural gas to produce hydrogen.

Usually the method used is steam-methane reforming, which uses superheated steam (over 1,300 degrees F) under pressure to turn methane into hydrogen, carbon monoxide, and carbon dioxide. More hydrogen is produced from reactions between the carbon monoxide and the steam (which itself contains hydrogen in the form of water molecules), and finally pure hydrogen is separated from the gas, removing the carbon dioxide and impurities. While the process is nearly always used with

methane, it will actually work to produce hydrogen from other substances as well, such as gasoline or ethanol.

Natural gas reforming can also be conducted with partial oxidation, which exposes the hydrocarbons in natural gas to small amounts of oxygen in order to oxidize them, producing hydrogen as a by-product. Steam-methane reforming is endothermic, meaning it requires heat (in the form of the steam), while partial oxidation is exothermic, meaning it produces heat as a by-product of its chemical reactions. It is also a much faster process of hydrogen production.

Natural gas reforming produces greenhouse gas emissions but fewer than are produced by the consumption of the fuel equivalent of the hydrogen being produced, so all other factors being equal—the greenhouse gas emissions associated with the storage, delivery, and sale of the fuels—hydrogen fuel produced in this manner is responsible for far fewer greenhouse gas emissions than fossil fuels, according to proponents. (There is some dispute about this.) Of course, hydrogen produced from hydrocarbon products like natural gas, even if cleaner in its life cycle, is still a nonrenewable fuel.

Sustainability and environmental concerns are not the only motives for proposing an alternative to oil-derived fuels, however. For those proponents for whom the appeal of hydrogen fuel is in freeing the United States of dependence on foreign oil, whether for political reasons or because of the price volatility of such oil, hydrogen fuel produced through coal liquefaction is a much improved energy source, despite the fact that the production of hydrogen by this method produces more, and worse, greenhouse gas emissions than gasoline use and refining does.

A small amount of hydrogen production uses methods independent of fossil fuels, but most such methods have not yet been implemented at the industrial scale, and in most cases there are no current plans to do so. (This is in part, though, because the country's hydrogen demand is adequately met by current production methods.) Hydrogen can be separated from water by various methods, including electrolysis or thermolysis, both of which require large amounts of heat. Electrolysis of water can be more cheaply implemented to produce hydrogen when it is performed at an industrial production facility or power plant where the production

of energy results in significant waste heat that can then be used to heat the water.

Since World War I, the ferrosilicon method of hydrogen production has been used by militaries in order to produce hydrogen to fill balloons. Water is added to sodium hydroxide and ferrosilicon in a pressure tank small enough to fit in a truck, and the resulting chemical reaction produces steam, sodium silicate, and hydrogen. More recently, experiments have been conducted on recently discovered properties of algae as a bioreactor. While experiments have suggested economic feasibility of commercial development, it has not yet been implemented.

Similarly, hydrogen can be produced by biomass, and the exploitation of biological waste to produce hydrogen has been suggested by green groups. A number of other methods have also been explored. For instance, in Spain, the Platacorma Solar de Almeria concentrates solar power to heat water in order to dissociate it into hydrogen and oxygen. The plant design is intended to be scalable.

Delivery Systems

A system of delivering energy via hydrogen is called *hydrogen economy*, a term coined in a General Motors talk in 1970 by University of Michigan professor Lawrence Jones. The term *fuel economy* refers to an energy delivery system; like gasoline, hydrogen is not an energy source itself but delivers energy when combusted or otherwise consumed. The hydrogen economy is a proposed replacement for the hydrocarbon economy, based on the argument that hydrogen use is cleaner and more sustainable.

Storing hydrogen is an important aspect of hydrogen economy. Because of hydrogen's light weight, over time it penetrates the liner of tanks used to contain it, which weakens them faster than tanks used to contain other compressed gases. The weight of the tanks used to hold compressed hydrogen also reduce a vehicle's fuel efficiency. This is less true of liquefied hydrogen, but liquefaction of hydrogen is a more energy-intensive process than compressing the gas, adding both to the financial costs of the final product and to the overall efficiency and environmental impacts.

Further, tanks of liquefied hydrogen must be extremely well-insulated and are prone to forming exterior surface ice, which accelerates corrosion. All of these problems are cited in support of

hydrogen fuel cells as an alternative to hydrogen-burning engines, but as mentioned above, hydrogen fuel cells at present are extremely expensive.

Large-scale use of hydrogen vehicles would require a hydrogen infrastructure in place. This requirement is why hybrid vehicles have been the most successful alternative to traditional fuel-burning vehicles: their difference is all in their design, but their usage is substantially the same and they do not require the support of new infrastructure. Electric cars, for instance, require access to charging stations if the driver is to drive further from home than a single charge can take him. Drivers of alternative fuel vehicles similarly need to be able to refuel their vehicles, which requires distributing hydrogen to filling stations (most practically, as an option at existing gas stations, though the more hydrogen is promoted as an alternative to gasoline the less this is in the interest of the Big Oil companies that own those gas stations).

At present, there are 23 hydrogen stations in California, only eight of which are open to the public, and a few dozen in the rest of the country. Development of hydrogen stations in the United States stalled after the 2008 financial crisis, and most 2009 federal stimulus money for alternative energy development went to other projects.

Infrastructure is repeatedly cited as the hardest obstacle to surmount. While expensive vehicles like electric cars can still be successfully launched because of the number of wealthy consumers willing to purchase, and the large payouts of those early consumers help subsidize production such that a later wave of cars may be sold at a slightly lower price, and so on until the cost of the vehicle is within reach of the general public, this is a slow process. Personal computers, for instance, took about thirty years to come down in price from impractical luxury item to something most of the working class can afford, and personal computers were not competing with an alternative product offering the same functionality at a lower price. A process that slow, or even a quarter as slow, cannot proceed at all if infrastructure does not also expand in order to allow adoption at great enough rates to bring the price down for subsequent purchasers.

On the other hand, greater fuel efficiency reduces infrastructure requirements because filling stations can be spaced further apart, and it thus takes fewer of them offering hydrogen in order to make a given

area driveable for hydrogen vehicle owners. Despite the problems facing hydrogen fuel use, at the 2012 World Hydrogen Energy Conference, many manufacturers announced plans to have hydrogen fuel cell vehicles available for sale in 2015, including Honda, Hyundai, and Toyota. Though Ford's hydrogen research projects in the past were canceled or ceased being funded, both Ford and General Motors have committed to introducing hydrogen fuel cell vehicles in 2015 as well.

Hydrogen Fuel Cells

Hydrogen fuel cells are remarkable devices that produce energy in the form of electricity through the chemical combination of hydrogen and oxygen. They have been used in industry and have powered spacecraft to the moon. Can hydrogen fuel cells power the average person's car with the efficiency and relative economy of gasoline-fueled internal combustion engines?

The fuel cell has basically three components: an anode, a catalytic membrane, and a cathode. Compressed hydrogen is let into the anode side of the cell. The anode splits the hydrogen into electrons and protons. The membrane (or electrolyte), which could be made of paper-thin gold or other metal, lets only the protons pass through. It blocks the electrons, which pass through a battery to drive an electric motor. Electrons then pass on around the fuel cell, reunite with the protons, combine with oxygen from outside

air and form water. Water is the only by-product—or emission—of the entire process.

History

By 2013, hydrogen fuel cells were thought of as one of the technologies that could break civilization free from fossil fuels. In the 1960s, the National Aeronautics and Space Administration (NASA) put fuel cells aboard Gemini spacecraft to power manned spaceflights of up to two weeks and supply astronauts with water (the by-product of energy generation). Fuel cells continued their work on Apollo moon missions and on Skylab and the Space Shuttle.

Despite that, rudimentary fuel cells have been around since 1838. That year Welsh lawyer and scientist William Robert Grove revealed his discovery that two platinum electrodes standing in sulfuric acid, their opposite ends sealed in containers of oxygen and hydrogen, would conduct a current of electricity between them. Grove himself was following up on the discovery in 1800 of William Nicholson and Anthony Carlisle that electricity could break water down into its components of hydrogen and oxygen.

Exactly how Grove's "gas battery," as he called it, worked was a matter of scientific debate. Only late in the 19th century did scientists identify the chemical processes involved in the fuel cell. Scientists including Ludwig Mond, Carl Langer, Charles R. Alder Wright, C. Thompson, Louis-Paul Cailletet, and Louis Joseph Colardeau continued research into the device, which they began calling a fuel cell. Most determined that, while fuel cells could produce energy, they were cost prohibitive for mass usage.

World War II, as it did so many other technologies, sped up research into fuel cells. Francis Thomas Bacon investigated using fuel cell stacks as energy producers in submarines to replace bulky storage batteries, but his work gained little traction. He continued periodic work on the cells in the 1950s; that work formed the basis of the NASA fuel cells.

Design

Any vehicle running on a hydrogen fuel cell will probably carry its own hydrogen. History buffs know that the German zeppelin *Hindenburg* was full of highly combustible hydrogen when it

exploded at Lakehurst, New Jersey, in 1937. (The United States had stopped selling Nazi Germany nonflammable helium by that time.) Proponents of hydrogen fuel cells say not to worry, though, because any hydrogen tanks in cars will be well-protected and well-grounded. Oxygen, obviously, is readily available. Cars already have grills and scoops to conduct air to internal combustion engines, and the basic components of fuel cell-driven cars will fit the spaces already designed into contemporary cars. But switching to fuel cell cars will not be as easy as swapping out parts.

Hydrogen Supply

Hydrogen is a component of 90 percent of the matter in the universe, yet it is not naturally occurring in a pure form. Before pure hydrogen can be used for any sort of power system, it must be separated from other elements. Traditionally, hydrogen has been taken from natural gas. High temperatures and high pressure separate hydrogen from carbons. The hydrogen is captured; the carbons become emissions, also known as greenhouse gases. Coal supplies most of the energy for the heating process, creating even more greenhouse gases.

At this writing, 95 percent of hydrogen in use is produced by this process. While the United States alone uses 10 million tons of hydrogen annually for industrial and scientific applications, experts say it will need 10 times that amount for hydrogen fuel cells to drive vehicles with anything like the ease of gasoline.

In short, the natural gas method involves using a fossil fuel to create a clean fuel from another fossil fuel, creating tons of carbon emissions in the process. Energy does result, but if eliminating pollution is the goal, the process is a loser. One method that could capture hydrogen from coal is to take the carbon dioxide resulting from the heating process and pump it underground, perhaps into exhausted oil or natural gas wells.

Another means of obtaining hydrogen is to strip it from water. That also requires intense heat, and most current water-heating systems use coal. Again, the pollution problem of energy goes unanswered. Nuclear power plants can conceivably create the heat but not until new generation plants come on line after 2020. They also pose other potential problems, such as the meltdown of the Fukushima nuclear plant after a tsunami hit Japan in 2011.

A researcher at the U.S. Department of Energy's Sandia National Laboratories in 2007 works with samples of a complex metal hydride, an advanced material for use in hydrogen storage systems that may be useful in hydrogen fuel cells for vehicles.

Storage and Distribution Problems

Hydrogen storage presents problems as well. Industry and science applications have long used liquefaction—turning hydrogen into a liquid by supercooling it. Liquid hydrogen tankers are a common sight on highways and railroads, and liquid hydrogen has powered spacecraft for years. But, again, the process is energy intensive and bulky, not conducive to the type of power needs that fuel cells in every car would demand.

Compressing hydrogen into storage tanks is easier to achieve, but tanks big enough to accommodate a trip of several hundred miles would be bigger than current gasoline tanks in cars. Tanks could also be made of “metal hydrides”—metal compounds that actually hold hydrogen and release it on demand—but they are inherently heavy and would add unnecessary weight to vehicles.

Traditional trucking of hydrogen—unless the semi tractor is itself alternatively powered—presents a fossil fuel catch-22: burning fossil fuels to

haul clean fuel created by using fossil fuels. The circular situation is somehow nonsensical.

Pipelines can be built for hydrogen transportation. Unlike oil, which will flow through a pipeline, hydrogen would have to be pressurized to move, and pipes would have to be reinforced to sustain the pressure. Thus, old pipelines could not be converted for this use; entirely new pipeline networks would have to be built.

Another possibility for hydrogen distribution is the isolation and capture of hydrogen at “hydrogen fueling stations.” As of 2013, this type of system was working at 36 stations in the United States. Having enough hydrogen stations around the country to fuel a hydrogen-powered transportation revolution is, of course, a major proposition. Car manufacturers estimate 11,000 hydrogen fueling stations coast-to-coast would be required to support what they call a “mature” consumer fleet of hydrogen fuel cell cars. Such an infrastructure would cost between \$20 billion and \$25 billion.

If all other obstacles were surmounted, experts say hydrogen fuel cells could propel cars for about 300 miles before needing a “fill-up.” Filling up would take much less time than a gasoline fill-up. That exceeds most electric car battery capacities.

However, one fuel cell is not sufficient. Fuel cells must be grouped in stacks to provide real power and range. Even then, fuel cell stacks seem durable only up to 75,000 miles before needing replacement. That is underwhelming given that the durability of most internal combustion engines allows them to go well over 200,000 miles.

Federal Planning

The many hurdles facing widespread use of hydrogen fuel cells would require government-scale planning, coordination, and incentives. The government has in the span of a decade both embraced hydrogen fuel cell planning and abandoned it.

During his two terms as president (2001–09), George W. Bush, a politician indebted to the oil business, posed as a champion of alternative energy. His budgets allocated \$18 billion for research, development, and promotion of alternative industries, \$3.5 billion of that in his last year in office.

Bush hailed hydrogen as a key to energy independence and a way to improve air quality. In 2003, he announced a widespread program to facilitate research and development specifically of hydrogen

fuel cells for cars. Bush also intended the research to prove the viability of fuel cells to provide energy for homes and businesses.

The Bush administration also presented the FreedomCAR initiative to develop efficient and safe techniques of hydrogen production and distribution. Bush's planners said that by partnering with the private sector, FreedomCAR would make fuel cell cars affordable, efficient, and readily available by 2020. The administration rolled out the program with a "Hydrogen Road Tour" featuring hydrogen cars made by General Motors, Daimler, Ford, Honda, Hyundai, Nissan, Toyota, Volkswagen, and BMW on a two-week tour of the United States. All the cars in the tour were experimental demonstration models.

Obama Alterations

In 2009, at the start of his first administration, President Barack Obama scuttled the Bush hydrogen initiative. Obama's energy secretary Steven Chu said the Bush program had not effectively solved any of hydrogen's major obstacles and that hydrogen would not be an effective replacement for gasoline by the Bush 2020 goal, or even a decade beyond that. While not ruling out any possibilities for hydrogen fuel cells, Obama preferred to allocate money to other energy projects that might prove successful sooner. Obama and Chu seemed more interested in promoting electric cars with onboard storage batteries.

Hypersonic Flight

Hypersonic speed is the flight of an airship at a speed in excess of 5.5 times the speed of sound (Mach 5.5) in the atmosphere of the Earth. When a plane, bullet, rocket, or other object of force exceeds the sound barrier, it "breaks the sound barrier," creating a loud noise. As an object moves from transonic to supersonic, it experiences compression of the atmosphere so that at sea level it reaches the speed of sound at 768 miles per hour (1,235.52 km/h) and thereafter a penetration occurs that is visible on photographs. The effect makes the plane or other object look like it is surrounded by an audio speaker.

Since the German V-2 rockets of World War II, developments in aeronautical engineering have allowed spacecraft and airplanes to attain hypersonic speeds. During the 1960s the Air Force developed the X-plane series of experimental aircrafts. A number of the pilots flying X-planes were able to reach hypersonic speeds. The X-15 plane still holds the world's hypersonic speed record at 4,520 miles per hour (7,274 km/hour). This was Mach 6.7.

The space shuttle orbiter, the Apollo command module, and Buran jets also attained hypersonic speeds. The Russian Buran spacecraft was a Soviet-era orbital spacecraft. Soviet official statements claimed that Buran delivered cosmonauts and space material to an orbiting spacecraft. The Buran was an unmanned vehicle that was used only once before it was destroyed in a hangar accident in 2002.

Scramjets

Scramjets are supersonic combustion ramjets. They are a variant of an air-breathing jet engine or ramjet. They use high speeds to force air to compress as well as decelerate before it is used in combustion. Inside a ramjet, the air is compressed and slowed to subsonic velocities while at the same time it moves at a supersonic speed. In contrast, the scramjet uses airflow that is supersonic so that its utilization of the compressed air is more efficient. Scramjets can operate at supersonic speeds. They have achieved speeds of Mach 12 and Mach 24 for unmanned flights.

The design of scramjets is similar to all jets. Propulsion (forward thrust) is achieved by gases expelled from the engine. The engine is fed air through an intake opening that is compressed and decelerated; this air is combined with a gaseous fuel to burn the atmospheric oxygen that is in the air received by the inlet. The burn produces heat, which energizes the gases to produce thrust through a diverging nozzle.

Scramjet designs are different from turbojet or turbofan jet engines. The typical jet engine uses a rotating fan-like component to compress air and the burn then heats it; or, it may use multiple rotating turbine engines to compress air. These numerous moving parts are more complicated, add weight to the aircraft, and are liable to failure. Scramjets, in contrast, lack moving parts; however, they must be accelerated to high speeds in order to achieve optimal cruising speeds. It would essentially be a scramjet in a rocket plane.

Boeing Company is a manufacturer of aircraft for both civilian and military purposes. It built the unmanned experimental Boeing X-51A scramjet in a consortium with Pratt and Whitney Rocketdyne. The X-51 is also known as the X-51 WaveRider because it uses its supersonic shockwaves to add lift. In order to achieve its hypersonic speeds, it was launched at flight altitude from a Boeing B-52 Stratofortress over the Pacific Ocean on its first flight on May 26, 2010. It achieved speeds over Mach 5, or over a mile a second. The speed is sufficient for flight from New York to Los Angeles in less than 40 minutes.

Other X-51 flights were conducted in August 2010, in 2011, and in 2012. Anomalies developed in these flights that caused a loss of flight control. In one case a control fin malfunctioned, so hypersonic

speed was not even attempted. A remaining X-51 was not used. Pundits called the flight failure a disaster or a catastrophe, although the flight data was recovered for use in further developments.

Congressional funding for X-51 vehicles was cut after the plane's viability was challenged on technical grounds. The goal of the research is to ultimately produce and operate a plane that takes off from a runway, moves to the upper atmosphere, and then travels at Mach 6 before slowing to land at its destination runway. Use of the technology for military spy planes is an expected outcome of the research. On May 3, 2013, the final X-51 flight set a new record and raised the likelihood of new funding.

Hypersonic flights were conducted in the Australia Outback by its military. A successful hypersonic transport system would allow flights from Australia to Europe in trips lasting 90 minutes. Hypersonic flight is fraught with enormous engineering challenges from the heat and stress caused by rocketing through the atmosphere at such high speeds. Before a space liner can be built, new cooling technologies for shielding crew, passengers, and cargo from the intense heat will be needed. In addition, the strength of the materials used in the wings will need to withstand very high temperatures as well.

Bans

Efforts to ban supersonic flight over the United States have been ongoing since the early 1970s. On April 27, 1973 (14 CFR Parts 36 and 91), the Federal Aviation Agency (FAA) banned civilian supersonic flight over the United States because of the sonic booms. The ban was due to intense protests from people on the ground who experienced supersonic shock waves. In recent decades the National Aeronautics and Space Administration (NASA) and others have sought to improve flight engineering so that the FAA would be persuaded to allow overland supersonic flights.

The FAA supersonic ban was applied to the Aerospatiale-BAC Concorde supersonic transport (SST). The Concorde (*le Concorde* in French) was a commercially built and operated supersonic passenger jet by a joint French and British combination. It was eventually granted landing rights in the United States at subsonic levels. It made supersonic flights to the United States as well as to other destinations in half the time of regular carriers. It

was phased out following a crash in 2000 and the decline in air travel in 2003 that followed the terrorist attacks of September 11, 2001.

Despite the ban instituted in the United States, research on hypersonic flight is being conducted by other nations, including a combination of European nations. Engineers and scientists are using advances in computers and knowledge of fluid dynamics to find ways to reduce or eliminate sonic booms and their attendant noise and damaging effects. Commercially, hypersonic flight would be accomplished with less fuel, reduced crew size, reduced airport fees, and reduced passenger fatigue, and it would provide many other benefits, including rapid transport of medical patients and medical supplies.

ICT, Social Impacts of

Information and communication technologies (ICTs) are increasingly used in transport to make travel more efficient and cost-effective. However, such pervasive technologies do not come without an array of social impacts attached to them. Radical technological changes have occurred in the early 21st century, creating high expectations both for developed and developing countries. In the United Kingdom, an example of a developed country, mobile phone ownership has increased from 36 percent in 2000 to 91 percent in 2011, while the number of land lines has dropped from 93 percent in 2000 to 81 percent in 2011. Similarly, Internet penetration has risen from 25 percent in 2000 to 76 percent in 2011 (63.8 percent in the European Union) and the increase of mobile phone data transfer has increased 40 times between 2007 and 2010.

In contrast, the Internet penetration rate in Asia is 19.4 percent and only 6.8 percent in Africa. The entry level fixed broadband connection cost is on average \$28 per month in developed countries, but it averages \$190 per month in developing countries. Linking these facts with social media, 48 percent of adults in the United Kingdom have a social networking profile, while 57 percent of mobile phone Internet users there visit social networking sites through their mobile devices, making it the most popular activity.

Analogous is the situation in Italy, where almost every individual has two mobile phones, while smartphones are used by more than one out of three users in countries such as the United States, Sweden, Italy, and Germany. At the same time, almost half of mobile phone users in developed countries including the United States, the United Kingdom, Germany, Italy, and Australia use their phone to access the Internet.

More than 700,000 mobile applications existed at the beginning of 2013 in the two main smartphone apps stores, demonstrating an immense interest by users, businesses, and governmental organizations for ICTs and mobile Internet. Although there are households in developing countries where five people share the same phone device, highlighting the diverse needs in various contexts, it is universally acknowledged that accurate and timely information has become highly valuable.

There are a few sectors other than transportation where accurate and timely information is valued more. This is reflected not only in the ever-growing number of transportation related smartphone apps but also in the actual infrastructure installed in vehicles, railway stations, airports, car parks, or bus stops. The overall purpose of ICTs is to make passenger and goods transportation more enjoyable, safe, efficient, and cost-effective. Hence, certain areas require constant attention by academics, practitioners, and policy makers, such as the

increased role of social media, the altered levels of social interaction, personal safety, privacy, surveillance, inclusive access, and the digital divide.

Positive Impacts

Established trends such as tap cards for public transport (for example, TAP card in Los Angeles, Oyster card in London, and Octopus card in Hong Kong), e-tolls in motorways or urban areas (for example, in Stockholm or Singapore), and emerging trends, such as experiential marketing (which is already utilized by car manufacturers to provide a personalized test drive experience and eventually boost car sales), are becoming the norm in developed countries. The use of a common social media profile facilitates such services both for users and providers.

Another key benefit gained through the wide use of smartphones and improved infrastructure, such as 4G-LTE networks, is the opportunity for users and transportation authorities to receive real-time updates about congestion, transportation service overcrowding, accidents, and road work through ICT sensors. The widespread use of social media has facilitated this trend and opened up communication channels between users who may not have been acquainted with each other previously.

Personal safety improvement during journeys through location tracking by friends and relatives is another positive impact for vulnerable social groups, whereas augmented reality gadgets overlaying the real world with virtual or computer-generated images (for example, Google Glass) claim to provide a wealth of information to the user in interactive ways. If these claims are realized, this may be invaluable for car drivers, public transport users, pedestrians, or cyclists, because they will be offered real-time key information leaving their hands free, thus increasing their safety during journeys.

These developments have also aided more direct communication with local authorities, overcoming traditional bureaucratic and hierarchical structures to report bottlenecks or maintenance issues requiring immediate action. This has created a bottom-up approach which supports well-being while promoting resilient infrastructure, as it has been proven to be helpful in emergency situations, for example during natural disasters in the United States or social unrest in the Middle East.

The major implication of ICTs for transport, though, is the creation of new valuable data sets,

because individuals are constantly on the move, generating new data that can be used to inform policies, research, or business decisions. This has been highlighted by the World Economic Forum in its review of the overarching principles for using personal data, which need to be revised to ensure that ICTs protect the rights of individuals while at the same time unlocking socioeconomic value in a hyperconnected and hypermobile world. Personal travel data have high intrinsic value individually but also collectively, and this is exaggerated with the development of Big Data alongside ICTs, which generate vast amounts of easy-to-transfer data in industries such as public transport, railways, air transport, or logistics.

Contrasting the state-owned urban public transport operators in France (for example, RATP in Paris) with the private corporations providing similar services in the United Kingdom (for example, bus companies in Leeds), it is easily understood that transport authorities in conurbations benefit from the collection and use of such data in both cases. Therefore, it is crucial to manage the increasing volume of data in such a way as to ensure that any potential benefits will add value to all stakeholders in urban environments.

Open Data initiatives target such objectives, and there have already been some nascent but interesting applications aiming at near-live train departure updates or road maintenance reporting on the move. The latter is fueling the exponential growth of the volume of smartphone and Web applications related to urban transport, which spans across sectors as diverse as logistics, taxis, cycling, car sharing, car parking, car insurance, accident reduction through location tracking, personalized travel coaching, street maintenance, carbon emissions reduction and other “green” initiatives, as well as the promotion of healthier lifestyles through travel reward schemes.

Negative Impacts

On the other hand, ICTs for transport may introduce negative impacts to particular social groups. Disabled people (mentally or physically impaired people as defined by the World Health Organization) face such impacts because many of the new services, infrastructure, or smartphone apps have not made any specific provisions for them (or they only provide a restricted version for their needs),

leaving them disadvantaged. The elderly or those who are not familiar with new technology form another disadvantaged group. These so-called technology illiterate may also be affected by the cost of new infrastructure or devices, which creates social inequalities linked to their income or home location.

Further, due to the increased time people have been observed spending using smart devices, a decrease has been reported concomitantly in time spent on actual interaction with family, friends, and colleagues. In addition, the fact that workers may be required to work while on the move because of the ubiquitous nature of ICTs creates a further strain in the attempt to retain a work-life balance.

This introduces the important topic of privacy and surveillance, which has been under-researched in this domain despite being already a concern for bus, coach, and truck drivers.

An associated contemporary policy debate within the European Union (EU) is about the “right to be forgotten” (that is, the option to completely delete one’s on-line data). No political consensus exists about this issue, yet, as it is opposed by U.S. corporations using individual data. Opponents of the right to be forgotten in the United Kingdom claim that the British economy may lose \$156.5 million to \$563.3 million (100 million to 360 million pounds) annually in lost revenue, whereas EU officials advocate that there will be additional annual revenues of \$3 billion (2.3 billion euros) as a result of increased consumer trust in online services.

While this debate remains, it is a fact that increased mobility has created a need for increased

identity construction and control. For that reason, data collection, standardization, storage, and sharing practices, particularly regarding cross-border transportation services, constitute priorities of authorities worldwide.

Nevertheless, a primary international concern with implications for transportation service quality is the remaining digital divide both socially and spatially. Table 1 examines this topic using selected rankings from the Economist Intelligence Unit and the Global Information Technology Report based on a mixture of factors, such as connectivity, human capital, sophistication of use of ICT, geographical dispersion, and legal and political considerations. These rankings show a clear distinction between levels of readiness between developed, emerging, and developing countries. Another important point is that, despite a decade of progress, several of the selected countries have not seriously advanced their global position, suggesting that a relative digital divide persists. The reasons for the digital divide are well documented in the academic literature and echo that of other socioeconomic divides.

Yet, expectations for emerging wireless and mobile technologies are high globally. Some observers conclude that several developing countries, having bypassed landline phones, will bypass the personal computer and leap-frog straight to mobile Internet. This is founded on the premise that mobile technology pledges improved opportunities for enhanced interconnectedness and transportation services to several social groups. Because of

Table 1 Global information technology report rankings

	Sweden	U.S.	India	Colombia	China	Haiti	Nigeria
2013 Out of 144 countries	3	9	68	66	58	141	113
2008–09 Out of 134 countries	2	3	54	64	46	n/a	92
2001–02 Out of 75 countries	4	1	54	57	64	n/a	75

this, R&D has not focused on population segments having joined the digital revolution at a slower pace, who have low-quality transportation and ICT infrastructure available.

Other social impacts to address are unintended consequences of ICTs for transport, energy use inequalities, and technological optimism bias, because it has been documented that it is not technology per se that matters the most but the use of technology for the wider social benefit.

Impaired Driving

Impaired driving describes the operation of any motor vehicle under the influence of alcohol or other intoxicating substances. It is also called driving under the influence (DUI), driving while intoxicated (DWI), operating while impaired (OWI), or operating a vehicle under the influence (OVI). Impaired driving in the 21st century can also include driving while talking on a cell phone, reading, or engaging in any other activity that affects concentration, reflexes, and handling of the steering wheel or other operation features while the vehicle is in motion. The U.S. federal government identifies this phenomenon as "distracted driving."

Impaired or distracted driving causes people to lose control over their vehicles and dramatically increases the risk of fatal accidents. Not only the driver but also passengers, people in other vehicles, pedestrians, and animals are all at risk for injury or death if an impaired driver is behind the wheel. The potential number of lives lost dramatically increases when someone under the influence of drugs, alcohol, or distracting technologies operates public transit. While most nations have laws that criminalize driving while under the influence of alcohol or other substances, governments are just starting to address distracted driving. Such laws may also apply to boating, flying an airplane, or operating farm machinery or horse-drawn carriages.

Impaired Driving

Nearly one-third of car crashes involve alcohol-impaired drivers; these impaired drivers cause roughly one-third of all traffic-related deaths.

Over half of the child passengers aged 14 years and younger who died in alcohol-related crashes were riding in a vehicle with an alcohol-impaired driver. Although over 1.4 million drivers were arrested for driving under the influence of alcohol or narcotics, those arrests make up only 1 percent of the 112 million self-reported episodes of alcohol-impaired driving among adults in the United States each year. Drugs such as marijuana and cocaine are involved in approximately 18 percent of motor vehicle driver deaths; these drugs are often found in the driver's system in addition to alcohol.

Driving while under the influence of alcohol (DUI) is considered a criminal offense in most nations. Due to strict laws and proactive education about driving under the influence, the number of DUI arrests in the United States has declined significantly. In the United States, traffic officers who have reason to believe that a driver is under the influence will ask him or her to perform certain tests, such as walking in a straight line and placing the tip of their finger on their nose. This is called a field sobriety test, developed by the National Highway Transportation Safety Administration (NHTSA). If the driver cannot pass this test, the traffic officer will test the driver's blood alcohol content (BAC) to determine whether alcohol is present in the blood and whether it is sufficient to impair driving. Younger car drivers are more at risk of being involved in a crash regardless of their BAC level, while older motorcyclists are more at risk. Penalties for DUI differ from state to state and increase in severity depending on whether the DUI incident led to fatalities. Most importantly, those drivers who face DUI penalties are often required to attend a prescribed number of counseling sessions or to join a 12-step program to address any substance abuse problems that they may have.

Distracted Driving

Distracted driving is a relatively recent phenomenon. Text messaging, in particular, is the most dangerous distraction as it requires visual, manual, and cognitive attention from the driver. Roughly 20 percent of crashes resulting in injuries are caused by distracted drivers. Using a cell phone while driving reduces the amount of brain activity associated with driving by nearly 40 percent; an Australian study showed that drivers who use handheld devices are four times more likely to get into injury-causing crashes.

History of Driving Under the Influence

Human beings have consumed alcoholic beverages and behavior-altering substances for at least 6,000 years. An impaired pedestrian or horseback rider, however, presents less of a safety risk than an impaired person behind the wheel of a motor vehicle. As cities developed and motor vehicles began to share the road with horse-drawn vehicles and pedestrians, impaired drivers presented a great danger to public safety.

The first law in the United States to prohibit drinking while driving was set in 1843 by the New York Central Railroad to prohibit drinking by employees while on duty. In 1897, the first DUI arrest took place in London. Taxi driver George Smith slammed his cab into a building while under the influence of alcohol. Smith pled guilty to the charges and was fined 25 shillings. In the United States, in 1910, New York was the first state to implement laws against operating motor vehicles while under the influence of alcohol. California and other states soon followed. While these early DUI laws prohibited driving while intoxicated, they did not provide a definition of intoxication, or what level of inebriation qualified as drunk driving. Police officers did not know how to assess a driver for drunkenness, nor did they have a convenient way to measure it.

As early as 1874, scientists could detect alcohol through someone's breath, but no one had put this discovery to practical use. Prior to the breath tests, police measured alcohol content through blood samples. Police had to transport the driver to special locations, contact physicians in the middle of the night to perform this procedure, and then safely store and transport the blood to a laboratory, which delayed results being delivered to the investigator and sometimes resulted in suspects getting away. In 1936, American biochemist and toxicologist Rolla Neil Harger from Indiana University developed a practical, portable machine to test human breath alcohol content. He called his invention the "Drunkometer." To measure a subject's blood alcohol content using the Drunkometer, Professor Harger had them blow into a balloon. The subject's breath sample was then pumped through acidified potassium permanganate, which would change color if alcohol was present in the sample. The more alcohol in the sample, the greater would be the change in color. Using a calibrated color chart,

it was possible to determine the alcohol in a breath sample with reasonable accuracy and from there to calculate blood alcohol levels. In 1953, former police captain and codeveloper of the Drunkometer Robert Borkenstein invented the Breathalyzer. This machine was an improvement over the Drunkometer in its compact size, ease of use, and reliability. The Breathalyzer is still used by police to measure blood alcohol levels.

In spite of having an instrument to measure blood alcohol content, police did not receive consistent training to determine whether a driver in custody could be impaired. As a result, many people stopped by the police for erratic driving either were cited for not following traffic safety laws or simply let go. In 1938, the National Safety Council established the Committee on Tests for Intoxication to gather information from select police departments on how they identify impaired drivers. In 1977, with the support of the NHTSA, the Southern California Research Institute evaluated the physical coordination tests used at the time to determine the inebriation of a suspect. This was the first significant assessment of the tests under real law enforcement conditions. Two hundred thirty-eight volunteers were subjected to a series of tests most frequently used in the field; researchers standardized objective clues and scoring criteria for the tests. The NHTSA standardized field sobriety testing; police officers across the United States now receive training to administer three tests—the one-leg stand, the walk and turn, and the horizontal gaze nystagmus—to determine inebriation according to consistent standards prior to administering a Breathalyzer test.

Despite advances in blood alcohol testing, people did not receive much education about drunk driving until the late 1970s. Because police officers finally had the tools to identify inebriated drivers and measure their blood alcohol content, lawmakers could write stricter DUI laws. In 1980, a California woman named Candy Lightner founded Mothers Against Drunk Driving (MADD) after her 13-year-old daughter Cari was killed by a drunk driver while walking home from a school carnival. The driver had three previous DUI convictions and was out on bail from a hit-and-run arrest two days before Cari's death. Lightner formed MADD to change attitudes about drunk driving and to push for legislation that increased penalties for driving under the influence of alcohol or drugs. MADD

also helped raise the minimum drinking age to 21 in most states.

Today, the legal drinking age is 21 in all 50 states. Convicted drunk drivers face a wide variety of penalties, ranging from jail time, fines, restriction or loss of their driving privileges, and increased car insurance rates. Only the state of New Jersey still considers a DUI without injury or death as a simple traffic violation. Each state has designated a blood or breath alcohol level to confirm a driver's state of intoxication and serve as a threshold for a criminal offense. Six states require physicians to report patients who drive while impaired, and another 25 states allow physicians to violate doctor-patient confidentiality to report impaired drivers. Some drunk drivers are ordered to have ignition interlock devices installed in their vehicles. These devices require a driver to breathe into a sensor attached to the dashboard; the car will not start if the driver's blood alcohol concentration is above a certain limit.

Special DUI courts provide substance abuse intervention for repeat offenders who plead guilty to driving while intoxicated. The courts enroll these offenders into a program that requires them to abstain from alcohol and wear a device to monitor and record any level of alcohol detected in their bodies. Some states, such as Ohio and Minnesota, issue special license plates to DUI offenders who are granted limited driving privileges for work or school until a court can reinstate full driving privileges. These plates are a different color from the standard-issue plates, start with the same letter, and do not have the same number of characters as regular plates.

Federal Aviation Regulation 91.17 prohibits pilots from flying aircraft with a BAC of 0.04 percent or more, or within eight hours of consuming alcohol, or while under the influence of any drug. This same prohibition applies to all crew members on duty. Commercial pilots charged with flying under the influence are terminated or may resign voluntarily; flying under the influence can result in loss of pilot certification or criminal prosecution under federal or state law.

Distracted Driving Legislation

To date, the most serious accident caused by distracted driving took place in September 2008. A Metrolink rail employee using a cell phone killed 25 people in a train crash in Chatsworth, California. This tragic accident caused the Federal

With the help of a computer-assisted DUI simulator, a college student experiences what it would feel like to attempt to drive under the influence. Such simulators are used in educational programs to help prevent impaired driving. Almost one-third of all car crashes involve alcohol-impaired drivers; these impaired drivers also cause as many as one-third of all traffic-related fatalities. In the United States, more than 1.4 million drivers are arrested for driving under the influence of alcohol or narcotics every year.

Railroad Administration to ban all rail employees from using cell phones or other electronic handheld devices on the job.

The U.S. Department of Transportation initiated a regulatory campaign against distracted driving. The campaign has involved prohibiting handheld device usage, including text messaging, while operating automobiles, trains, planes, or commercial vehicles. This campaign began in 2009, when President Barack Obama signed an executive order directing federal employees not to engage in text messaging while driving government-owned or privately owned vehicles while on official government business. The order also advised federal contractors and others doing business with the government to adopt and enforce their own policies outlawing texting while driving.

In September 2010, the Federal Motor Carrier Safety Administration (FMCSA) banned commercial truck and bus drivers from texting while

driving. In November 2011, it banned all handheld device usage by commercial drivers. In February 2011, the Pipeline and Hazardous Materials Safety Administration (PHMSA) banned texting on electronic devices by drivers operating motor vehicles containing hazardous substances.

In 2009 a Northwest Airlines flight crew overshot their destination by 150 miles due to distraction from a laptop. In response, the Federal Aviation Administration (FAA) advised all air carriers to create and enforce policies that limit distractions in the cockpit and keep pilots focused on the skies.

In the United States, all of the 50 states have at least one law criminalizing handheld device usage while driving, texting while driving, or both. Unfortunately, current laws do not always address all drivers in all situations. Some laws only criminalize device usage or texting while driving for a particular segment of drivers, such as teenagers or bus drivers. Other laws criminalize distracted driving in certain

locations, such as around schools or in areas with heavy pedestrian traffic. Enforcement of these laws is inconsistent, as a driver stopped by the police for erratic driving who is not captured on video can easily hide the device.

DUI Investigation and Arrest

Law enforcement officers come in contact with impaired drivers in multiple ways. The officer might respond to the scene of a car accident, notice that the driver is impaired, and begin an investigation. Sometimes police receive a report from a concerned citizen who describes a car driving erratically, locate the driver, and pull them over. An officer on patrol might observe suspicious driving or a series of traffic infractions committed by the same driver. Finally, a police officer might stop a vehicle for a lesser offense, notice signs of intoxication, and begin an investigation.

Sobriety checkpoints involve traffic police or highway patrol stopping either every vehicle or every *n*th vehicle on a public roadway to investigate the possibility that drivers may be too impaired to drive. These checkpoints are often set up late at night, the very early morning hours, weekends, or during holidays or events that may involve heavy drinking. Checkpoints are often situated near the exit points at public events to prevent the simultaneous release of drunk drivers onto the road. If the law allows, the police can give a breath test to all drivers. If the officer cannot perform a quick test but has reason to suspect intoxication, the officer may require that the driver exit the vehicle and take a sobriety test to prove mental and balance skills. If the driver fails that test, the officer can then administer a Breathalyzer test.

Sobriety checkpoints have come into conflict with the Fourth Amendment of the U.S. Constitution, as some believe they violate the right of persons to be secure against unreasonable searches. In 1990, in *Michigan Department of State Police v. Sitz*, the U.S. Supreme Court found sobriety checkpoints to be constitutional; Chief Justice William Rehnquist argued that the state interest in reducing drunk driving outweighed individual privacy. The NHTSA issued a report that provided recommended checkpoint procedures in line with federal and state legal decisions to prevent violations of constitutional and civil rights. Though the Centers for Disease Control and Prevention and the independent organization

Public Health Law Research both issued reports proving that sobriety checkpoints reduce the number of alcohol-related driving fatalities by at least 20 percent, most states employ the checkpoints sparingly. Ten states do not allow sobriety checkpoints at all under their state constitutions.

The NHTSA has published a list of 19 DUI symptoms to train officers to identify impaired drivers. Each symptom includes a percentage figure that indicates the statistical chances that a driver is over the legal blood alcohol content limit. Symptoms are listed from most likely to indicate intoxication (straddling center or lane marker) to least likely (headlights off). If the officer observes one or more of these symptoms to build reasonable suspicion to legally justify investigation and detention, he/she will stop the car, approach the driver's window, and ask some questions. During this phase the officer will note whether he/she detects alcohol on the driver's breath, slurred speech, watery or bloodshot eyes, flushed face, or other physical indications of intoxication.

If the officer has reasonable suspicion to legally justify further detention and investigation, he/she will ask the driver to step out of the vehicle for a sobriety test. The three validated NHTSA tests are (1) the horizontal gaze nystagmus test, which involves following an object such as a pen with the eyes to determine eye movement reaction; (2) the walk-and-turn, designed to measure a person's ability to follow directions and remember a series of steps while dividing attention between physical and mental tasks; and (3) the one-leg stand. These tests indicate a probability that a driver is at or above the legal blood alcohol limit.

If the officer has sufficient probable cause that the suspect has been driving while intoxicated, the suspect will be arrested, handcuffed, and transported to the police station. At the station, the police will test the driver's blood, breath, or urine for alcohol or drug content. If the tests show that the driver's blood alcohol content is not at or above the legal limit of 0.08 percent, the driver is released without any charges. If not, the driver will either be kept in a "drunk tank" until officers believe he or she is sober enough to be released on bail, or they will be subject to appear in court at a future date.

Driving Under the Influence of Drugs

Driving under the influence of any drug can impair one's motor skills, reaction time, and judgment.

Many over-the-counter or prescription medications can make a driver sleepy and cause them to lose control of the vehicle, thus causing an accident. According to the NHTSA, more than 16 percent of weekend, nighttime drivers tested positive for over-the-counter, prescription, or illegal drugs. Nearly 20 percent of fatally injured drivers tested positive for at least one drug. In spite of the increase in “drugged driving” arrests, specific drugged driving legislation has lagged behind alcohol-related driving legislation.

Few state laws identify “drugged driving” as a condition distinct from DUI; if they do note the condition, they simply identify it as “driving when a drug renders the driver incapable of driving safely” or “causes the driver to be impaired. As a wide variety of drugs exist on the market, whether legal or illegal, law enforcement and other researchers have not come to consensus on which drugs to study in order to determine drug levels that would cause impairment. Also, some drugs remain in the body for days or weeks after initial ingestion.

Forty-four states have established Drug Evaluation and Classification Programs, designed to train police officers as drug recognition experts (DREs). Similar to sobriety field test training, officers learn to detect characteristics in a person’s behavior and appearance that may be associated with drug intoxication. If the officer suspects drug intoxication, he/she will bring the driver to the police station where a blood or urine sample will be taken and submitted to a medical laboratory for confirmation. Seventeen states have passed “per se” laws, which state that it is illegal to operate a motor vehicle if there is any detectable level of a prohibited drug (such as marijuana or cocaine) in the driver’s blood.

The DRE protocol is a 12-step process to establish through a series of tests whether an impaired driver was driving under the influence of drugs. This process is more time intensive than the sobriety field test and the Breathalyzer, which may be a reason why most states do not have separate legislation for drugged driving. The first four steps of the process include assessments from the sobriety field test, as well as taking the driver’s pulse. The DRE will ask a series of standard questions in relation to the driver’s health and recent consumption of food, alcohol, and drugs, including prescribed medications. The DRE will observe the subject’s attitude, coordination, speech, breath, and face. The

DRE will also determine whether or not the driver’s pupils are the same size. If the DRE believes that the driver may be suffering from a significant medical condition, the DRE will seek medical assistance for the driver immediately. If the DRE believes that the driver’s condition is drug related, he/she will continue the evaluation. Further steps in the investigation include an eye examination, vital signs and second pulse, examination for muscle tone, a check for injection sites, and a third pulse. The DRE will then read the driver their Miranda rights and ask the driver more targeted questions about their drug use. At that point, the DRE will form an opinion as to whether the driver is impaired. If the driver is impaired, the DRE will request a urine, blood, or saliva test from the driver.

DUI Outside the United States

The illegal BAC for most of the United States is higher than all other first world nations, as identified in a report published by the NHTSA. At the same time, the minimum purchase age for alcohol is older in the United States than in most other first world nations, while the minimum driver license age for most countries is older than the minimum legal purchase age for alcohol. Penalties for DUI in other countries are often much stricter than in the United States; they range from heavy fines, revoking driving privileges, prison, or house arrest under electronic surveillance. Some countries require proof of successful alcohol or substance abuse counseling prior to returning driving privileges. Police in other countries have more authority to stop and test drivers for BAC at will.

Prevention and Interventions

Reducing the frequency of drunk driving in the United States requires education and community-based approaches for treatment. The National Institute for Alcohol Abuse and Alcoholism states that environmental interventions are most helpful to eliminate drinking and driving altogether. As young drivers are most likely to get into car accidents, the most successful solution to reduce impaired driving and DUI fatalities was raising the minimum drinking age to 21 years of age. This federal law, in conjunction with MADD, has led driver education programs and high schools across the United States to include information about substance abuse, impaired driving, and its legal consequences in curricula. Law

enforcement officers visit schools and talk to students about DUI-related accidents they have witnessed, sometimes even bringing in the windshield or dented car door for added effect. If this cannot be arranged, students watch videos that help them reach the same conclusion—that DUI is dangerous and not worth the risk.

MADD inspired the creation of a student chapter—Students Against Drunk Driving, or SADD—in 1981. SADD has become the leading peer-to-peer youth education and prevention organization, with thousands of chapters in middle schools, high schools, and colleges. It endorses a firm “No Use” message related to alcohol and other drugs and provides helpful advice to students who do decide to attend parties where alcohol is served. SADD has taught high school and college students about “designated drivers,” how to collect car keys from everyone at a party if alcohol is served, and encourages people who had too much to drink to spend the night at a friend’s house if necessary before getting back on the road.

In spite of the lack of “drugged driving” legislation, aggressive substance abuse education has taken place in the United States since the mid-20th century. Although use of illegal drugs among youth has decreased in the United States, more young people are abusing psychiatric drugs and over-the-counter medications, which also have an impact on their ability to drive safely. Recently, SADD changed its name from Students Against Drunk Driving to Students Against Destructive Decisions to include drug use and other self-destructive behaviors as well as risky impaired driving.

City, county, and state employment application procedures often include requesting information from the Sheriff’s Department and the Department of Motor Vehicles about applicant driving history and criminal background, if any. DUI offenses of any kind may limit a job seeker’s employment opportunities, especially if they are applying for positions in education, health care, or other human services professions where they may be required to transport people or operate vehicles or heavy equipment while on the job. DUI is still perceived as a character flaw in many parts of the United States, as well as a criminal offense. Knowledge that DUI offenses stay on one’s record and can affect one’s job opportunities may make people think twice about driving under the influence.

Americans work longer hours than people in other countries and are often expected to multitask while on and off duty. As they balance work, education, and child care, they frequently drive distracted and medicated. Perhaps the most helpful intervention that government can provide for drivers to reduce DUI arrests is to provide more child support for single parents and low-income families.

Incident Detection Systems, Airplane

The rise in the frequency and seriousness of incidents and accidents in modern aviation history

has heightened awareness of aviation safety, spurring the development of incident detection systems. Among the most serious incidents that threaten aircraft safety are collisions with terrain or other aircraft, runway incursions, weather hazards, and aircraft fires. Incident detection systems have advanced with technological developments, accident investigation and safety recommendations, improved flight crew and air traffic control (ATC) training, and new government and industry requirements.

The International Civil Aviation Organization (ICAO) and U.S. Federal Aviation Administration (FAA) classify occasions associated with aircraft operation that affect or threaten operational safety based on seriousness. An aviation accident is defined as an occasion associated with aircraft operation that results in fatal or serious injury or serious aircraft damage or structural failure, or an inaccessible or lost aircraft. An aviation incident is defined as an occasion associated with aircraft operation that affects or threatens operational safety without meeting the qualifications for classification as an accident.

Fire and Weather

Aircraft fires pose a significant danger due to multiple potential fire sources, the confined space of an aircraft, and the difficulty of escape, especially if an aircraft is airborne. Automatic heat- and smoke-sensing equipment enable the early detection of aircraft fires, allowing flight crews or automatic equipment to initiate countermeasures before a fire becomes uncontrollable. Response can be manually initiated by the flight crew or automatically initiated by computer-controlled equipment, based on the alert location.

Heat-sensing fire alert systems are commonly used in engines and auxiliary power units (APUs), high temperature bleed air leaks, and landing gear bays, whereas smoke-sensing systems are commonly used in toilet compartments and avionics bays. Cargo holds utilize both types of systems. Sensing equipment alerts sound either locally at the source where heat or smoke is detected or at a central location. Automatic sensing equipment does not detect fumes, leaving their manual detection and alert primarily to the flight crew.

Adverse meteorological conditions are a common and significant safety threat to arriving, departing,

or in-flight aircraft. Two of the most dangerous meteorological threats are icing and wind shear. Ice detection and protection systems protect both the aircraft surfaces, such as the wings, and the aircraft engine. Deicing systems detect and remove ice that has already accumulated. Anti-icing systems are designed to prevent ice from forming but are also commonly used as deicing systems as well. Common systems include thermal deicing and anti-icing systems and pneumatic deice boots.

Wind shear generally refers to the presence of rapid changes in prevailing wind currents. The meteorological phenomenon known as a microburst has been known to produce strong wind shear and has been targeted as the cause in several well-known aviation accidents. Wind shear can cause aircraft to suddenly accelerate airspeed and ascend. Pilot awareness of wind shear is critical to avoid the manual reduction of engine power, which will result in a sudden deceleration of airspeed and loss of altitude as the aircraft emerges from the wind shear.

Most aircraft rely on onboard predictive wind shear sensor systems based on microwave radar, Doppler LIDAR radar, or infrared. Many airports are also equipped with ground-based systems such as the Low-Level Wind-Shear Alert System or the Terminal Doppler Weather Radar system. Radar weather detection systems can also alert flight crews or air traffic controllers to other potential incidents arising from the presence of turbulence, storms, or lightning.

Collision Avoidance

Collision avoidance has become a primary aviation safety issue due to air traffic and airport congestion, as well as predicted air travel growth. Future airspace and airport capacity increase through programs such as the FAA's NextGen, which will place aircraft in greater proximity, will only increase the future need for incident detection systems that identify potential ground and in-air collision incursions.

Runway incursions are common potential sources of ground-based collisions. The ICAO defines a runway incursion as any incident involving the incorrect presence of an aircraft, vehicle, or person on a runway (the designated surface for aircraft takeoff and landing). The FAA uses a similar definition with the exception that the term *surface incident* is used if there is no potential for collision

Proteus, a tandem-wing research plane, has been used by the National Aeronautics and Space Administration for tests of collision-avoidance flight systems for unmanned aerial vehicles using a radar unit installed underneath the aircraft's nose cone.

with an aircraft, such as if the runway where the incursion takes place is empty.

There are numerous causes for runway incursions, broadly categorized as those originating from pilot error, air traffic control error, or other conditions. Examples include pilot noncompliance with ATC clearance, the issuance of and compliance with invalid ATC clearance, or ground vehicle runway incursion without ATC clearance. Contributing factors can include poor weather or visibility conditions, flight crew unfamiliarity with the airport, airport design and function, language issues, heavy workloads, and other distractions.

Alerting air traffic controllers and flight crews to potential or actual runway incursions is vital, as aircraft on runways are often traveling at high rates of speed, increasing potential for damages, injury, and loss of life. Runway incursions have been responsible for some of the world's deadliest aviation accidents, such as that which occurred at the Tenerife airport in 1977. Computer-based systems in use

to alert to potential or actual runway incursions include traffic alert and collision avoidance systems (TCAS), runway awareness and advisory systems, enhanced vision systems, the FAA's Airport Surface Detection Equipment Model X (ASDE-X), and Northrop Grumman's Airport Movement Area Safety System (AMASS).

Aircraft-based, in-air collision incident detection systems were designed to work independently of those ground-based systems employed by ATC as a safety backup. Ground proximity warning systems and enhanced ground proximity warning systems, also sometimes known as terrain awareness and warning systems, prevent collisions with terrain. TCAS are the most common detection systems used in private and commercial aircraft to avoid in-air collisions. Many military aircraft are also equipped with TCAS or modified TCAS to enhance safety.

TCAS systems provide flight crews with traffic and resolution advisories. A traffic advisory alerts the flight crew to nearby aircraft and their locations to allow for visual acquisition. Resolution advisories provide the flight crew with recommended escape maneuvers. TCAS I systems provide only traffic advisories, and newer TCAS II systems provide both types of advisories.

TCAS systems utilize surveillance, collision avoidance system (CAS) logic, and pilot displays. TCAS analyzes aircraft transponder information received from other aircraft in proximity to determine whether a collision is possible and whether evasive maneuvers are necessary. Traffic and resolution advisory displays visually and audibly show the flight crew proximate aircraft, threat level, and necessary maneuvers. Common problems with TCAS include the issuance of so-called nuisance advisories in certain situations where there is no danger of collision or need for escape maneuvers.

Newer developments in collision avoidance systems include Automatic Dependent Surveillance-Broadcast (ADS-B) technology, TCAS-ADS-B hybrid systems, and Airborne Collision Avoidance System (ACAS-X). The FAA began development of ADS-B in the 1990s. The ADS-B system is based on aircraft self-reporting of necessary flight data, whereas hybrid systems allow TCAS to utilize ADS-B gathered data. ACAS-X was under development by the FAA as of 2013, with many European countries also expressing interest. This new system

represents a complete redesign rather than an overhaul of TCAS.

Incident Detection Systems, Automobile

Incident detection systems include a variety of automatic incident detection (AID) equipment intended to reduce risk on busy roads and highways. The idea is to install a substantial network of video cameras to provide continual and complete coverage of the movement of traffic and to link this to a computerized system that will identify any incidents—collisions or breakdowns, for example—that would compromise safety and, consequently, automatically trigger a traffic-calming signal in the affected area. The same system would also be used to determine when the incident has been resolved and when normal driving conditions can be resumed. The ability of traffic authorities to deploy this kind of technology has only been developed in recent years and problems persist, not least of which is cost.

One of the better-known systems is MIDAS—the Motorway Incident Detection and Automatic Signaling—which was introduced on the M25 circular motorway around in the United Kingdom in 1997. Previous versions of this system had been trialed on the M1 and M4 routes, which are also extensive multilane highways along which cars can move at up to 70 miles per hour (mph; 113 kmh) and along which personal automobiles and large trucks share space. The volume of traffic and the amount of territory involved mean that the likelihood of the police or emergency services being able to respond in time would be slim, which means there is a need for technology. This approach enables the state to retain control of road traffic management, increasing productivity of the personnel employed and incorporating elements from the private sector that might not otherwise be available.

The Technological Challenge

That incident detection systems have only recently been introduced and are still under development indicates the complexity of the technology involved. There are various elements that must be balanced with each other and, as is often the case, it is in the connections between two or more subsystems that most difficulty can arise. Governance issues are usually quite straightforward to manage, with the road system involved being under the jurisdiction of a specific national or regional level authority (as privatization of roads is not widespread) and the service provider generally being a private-sector concern under contract for a specific project and its upkeep. However, there is a need for a close relationship between the service provider and the authority because of the importance of the work, which concerns not only safety but the legal use of the roads. Sumitomo's AID is part of a suite of services, including a license plate recognition system and a traffic flow control system. It can monitor both fast and stopped vehicles, those traveling in the wrong direction, those frequently changing lanes, and excessive congestion. The network must be established and maintained, the video captured at a central location, processed so that only relevant incidents are brought to a higher level of attention, the correct response elicited and then implemented. At the same time, there is a need to integrate the results with those of neighboring systems, if these are in operation. It is also necessary

to develop a database of video footage in a format permitting additional analysis such that awareness of the need to take action and the type of action to take will be constantly refined and improved. To some extent, data gathered from one location may be used in analyzing conditions in other locations, although there are issues relating to the ownership of data, its means of analysis, and transferability to other locations.

In addition to the hardware and connectivity issues, there is also the conceptual basis of the software systems to incorporate into the overall network. Although it is often imagined that traffic resembles a liquid, in that it could be made to flow efficiently if only the correct system of pipes and connections could be found, in fact, traffic should be better thought of as a gas, which expands to fill whatever space is available and attempts to escape through any defects in the system. To tackle this complexity, fuzzy sets and neural networks are among the approaches employed, while the development of new algorithms aimed at understanding and predicting events has benefited considerably from the advent of low-cost and massive computational power. As they have been successively introduced, these are systems that would not have been possible even a few years earlier.

Spread of Automated Highway Systems

The forerunners of incident detection systems can be found in the partnerships between General Motors and the government from the time of the 1939–40 World's Fair. The concept initially was one of personal freedom for the driver, who could relax with his family (as driving was generally a gender-distinct activity) while the car drove itself. In conjunction with the Radio Corporation of America (RCA), General Motors was able to demonstrate self-driven cars going around racetracks. These early initiatives were developed into joint research programs featuring the Bureau of Public Roads and later the Federal Highway Administration (FHWA). However, national-level initiatives were ceased in 1981 as the result of a new ideology seizing control of government, and the focus on new technology switched to Europe and Japan, where serious attempts were not begun until the 1960s but which then overtook American efforts. European activities in this regard were primarily international in nature, owing to the relative and growing closeness

in cooperation between some western European countries that shared important road systems and because of the desire to obtain economies of scope and scale in research. In Japan, the period of rapid economic development was administered and overseen by the Ministry of International Trade and Industry, which developed close relationships with large corporations that were encouraged to enact state-level development priorities. Subsequently, new research partnerships in the United States have led to return of attention to that country as one of the leaders in incident detection system development and deployment.

The Panopticon

The French philosopher Michel Foucault described a prison system in which cameras watched all the convicts all the time. Once the convicts believe that everything they do will be seen and punishment will meet any transgression, they will obey the law at all times, at which point there will be no need for anyone to be monitoring the cameras or for the cameras to be working at all. This link between technology and social control is one that troubles many people on the basis of civil liberties. Although the purpose of the system is safety and few people would argue that there is not a need to reduce risks in a very dangerous environment, it has become evident that data obtained can be used in a wide range of applications and, since storage of data has become very cheap, could be maintained on a more or less permanent basis. The use of automated data mining techniques could be used not just to identify when crimes or misdemeanors have been committed but also could monitor the movements of individuals and use this in ways that many people feel contravene the privacy that they believe they have a right to enjoy.

A related issue is the right that some people feel they have to drive their automobiles in the way they choose, within the context of the existing laws and common sense. This is particularly true in the case of individualistic societies such as the United States, where driving an automobile at all can be construed as an act of personal freedom. There is little doubt that traffic planners would generally prefer automated systems to take preference for the same reason that aircraft are safer to fly when they are under the control of the autopilot rather than the human pilot. If all automobiles could be

controlled, then more could be safely arranged in proximity to each other at an even pace, resulting in quicker and safer journeys, more efficient use of resources, and reduced costs of traffic management and automobile repair and maintenance. These measures will presumably be introduced incrementally. Some public transportation systems already work on this basis.

Induced Travel

New or expanded transportation capacity encourages people to travel more. That is the essence of induced travel. It can be associated with any mode of transport, and its existence has been recognized since before the automotive age, but attention and controversy have focused on induced car travel. In recent years, more precise measurement of induced traffic has accompanied proposals to acknowledge its effects on travel demand forecasting and hence on road construction plans.

The terminology of induced travel is not always consistent. "Generated travel" can mean the same thing, although some writers distinguish between new travel "induced" by new road capacity and travel diverted to the new route from other roads or other transit modes. Both new and diverted travel can call into question the benefits of new roads, but they raise different issues. Diverted traffic is best known through economist Anthony Downs's influential postulate of a "triple convergence" produced by new road capacity, which induces travelers either to switch the time of their trips, their route, or their transport mode. The switch in transport mode in particular raises the question of whether money spent on road construction might merely be subsidizing a shift from mass transit, to little net benefit.

Even broader questions arise where entirely new travel is induced by new roads. This new travel might comprise either longer commutes or additional trips. The most obvious cases are new suburban bypass highways that stimulate exurban residential or commercial real estate development. In many places these new roads have been built as economic development tools, with the intention of inducing traffic, that is, of drawing more motorists to planned new residences and businesses. Critics characterize these roads as subsidies for suburban sprawl.

When too many cars squeeze into too few lanes, congestion results. The obvious solution is more road space. Road construction has in fact been the reflexive response to congestion throughout the automotive age. During the 1920s, the first time that automotive traffic threatened to overwhelm city streets, some transportation planners observed that new roads seemed to attract so much new traffic that they failed in their purpose of relieving congestion. Their views had little effect on transportation policy, however. Car use was growing rapidly, and the fact that new roads quickly filled up was generally understood to mean that road capacity needed to expand even faster. During the rapid post-World War II expansion in auto ownership and road capacity, the same beliefs and policies continued to prevail, despite motorists' complaints that new freeways were filled to capacity as soon as they opened.

Induced travel becomes a problem when it calls into question the value of new road construction (or of new transit capacity). By the late 20th century, it was standard practice to calculate the economic benefits of new roads largely in terms of reduced

time lost to traffic congestion. However, critics pointed out that induced traffic might negate those gains, at least in part. Their slogan, “You can’t build your way out of congestion,” offered a direct challenge to the established logic of road construction. The difficulty in measuring induced traffic, in addition to the influence of vested interests committed to road construction, meant that these critics’ views long had little influence on policy.

Only since the 1980s have there been substantial efforts to measure induced travel. The question of whether it significantly altered traffic forecasts was long in dispute. Although there is no consensus about the precise elasticity of travel demand, statistical studies since the early 21st century have furnished increasingly persuasive evidence that it is measurable and significant—large enough to call into question some of the claimed reductions in congestion from new road capacity.

Transportation policy makers have generally been reluctant to acknowledge this evidence or to change their formulas for assessing the value of new roads. However, the traditional policy of “predict and provide”—that is, estimating traffic growth and building road space for it—has come under assault for various reasons, above all because many governments have found it impossible to pay for the continuing expansion of road capacity. Some critics point to evidence of induced traffic as a reason to limit road construction, because induced traffic accelerates the rate at which new roads reach their capacity.

Scholars and policy makers who accept the significance of induced travel have made various recommendations to reform transportation policy. The most obvious is to develop widely accepted formulas to predict the extent of traffic induced by proposed projects and to factor this induced traffic into any calculations of reduced congestion. Critics of road expansion argue more broadly that road construction should no longer be promoted as congestion relief. Advocates of road pricing believe that the problem would be solved if motorists had to pay an appropriate toll or fee for the privilege of speedier travel.

Information and Communications Technologies (ICT)

See ICT, Social Impacts of

Information Technologies and Transportation

Information technology is used in transportation for managerial, planning, and traveler purposes: operations (for example, running trains back and forth), maintenance (for example, repairing potholes), service management (ensuring safe and efficient road speeds), safety and security (monitoring and responding to potentially nefarious activities), and traveler information (maintaining mobility). This article identifies essential information technologies, current and emerging, for transportation.

Smart Infrastructure

Highways, streets, and arterials around the world are increasingly equipped with sensor technologies

to measure traffic throughput. Common sensor technologies include the following:

- Electronic tag readers placed at specific intervals determine travel time between specific points using the agglomerated data from all vehicles.
- Inductive loop detectors are in-asphalt vehicle detectors that count vehicles, often with classification type, as they pass over the loops, thus interrupting its electric flow. When two or more loops are spaced apart on the same road, they measure traffic speeds and throughput.
- In-road sensors in Germany are used to toll vehicles by calculating the vehicle weight, pollution class, and number of axles, while connecting to in-car sensors for billing.
- Traffic throughput data is used both to report speed and congestion conditions and, more recently, to predict traffic jams. An algorithm developed by IBM predicts traffic jams up to 45 minutes beforehand using this sensor data; in Singapore, this information prompts the adjustment of traffic lights to encourage traffic flow. As this prediction tool is further developed, it will likely be deployed elsewhere.

Next Generation Air Traffic Control (NextGen) is a U.S. initiative to replace air traffic controls from ground-base technologies to satellite monitoring. It will give airplanes more accurate depictions of their locations, reducing spacing requirements to make room for increased air traffic. In addition, air traffic controllers will be able to communicate through both voice and data transmissions, instead of the current voice-only system, allowing them to handle more aircraft and increase airport capacity. NextGen is presently being built and expected to be completed by 2025.

Computer-enhanced parking systems are being developed in several cities to improve the efficiency of the parking process. Sensors are placed in the asphalt in each parking space to alert spot-seeking drivers with smart phones of their availability. The sensors can also notify both car owners and traffic police of expiring time allotments. Some cities use the sensors to adjust parking rates by time of day

and incentivize side-street parking, and the systems allow drivers to pay by mobile phone.

Smart parking technology is still in development and faces several challenges:

- The sensors are not 100 percent accurate, leading to some errors.
- There is a delay in getting information from the sensors, through the processing servers, and out to drivers.
- Enticing drivers to look at their phones while driving presents a hazard to themselves, other drivers, and pedestrians.

Smart parking is being piloted in several major U.S. cities, including Los Angeles, San Francisco, and New York, and will likely be deployed more widely soon.

Bridges are vulnerable to cracks and erosion, among other defects, and must be monitored continuously to ensure their safety. Networks of sensors are placed on bridges to detect significant movements, corrosion, and cracks and to report that data to inspectors. The information is used in modeling software to determine the extent of the issue and whether repairs are necessary. This technology can help avoid a major catastrophe, such as a collapsed bridge.

Traffic Reporting

Traffic is reported to news outlets and the public by agglomerating information from several sources:

- Traffic alerts are developed by those with visual perspectives of the roadways, including helicopter-based reporters, traffic cameras, and bridge operators.
- Historical data lends perspective on typical rush hour commute times or traffic patterns during major events.
- Real-time information systems on major roadways use networks of roadway and vehicle sensors to measure traffic flows.
- Crowdsourcing gathers data from public mobile phones and the Global Positioning System (GPS) to measure traffic movement patterns in a region.

These data are collected and analyzed then reported to the public through news media, GPS data

receivers, and Internet tools such as Google Maps. They are also used to generate the information posted on highway variable message signs, which inform drivers of traffic news specific to their locations (for example, “45 minutes to downtown”).

Car and Road Technologies

New technologies are being developed that warn drivers of hazardous road conditions using wireless communications between road sensors and in-car dashboards so that, for example, icy pavement warnings may appear on drivers’ dashboard displays. In the future, roads may regulate car speeds or activate brakes to avoid collisions.

Vehicle-to-vehicle communications are also being developed so that cars become aware of one another as they drive in parallel lanes or navigate the same intersection. By integrating this perception into car control, this technology would allow for tight but adequate spacing between cars on highways, increased braking speed, and safer left turns at intersections.

Specific computer-assisted vehicle technologies currently in use include the following:

- *Radar.* Some cars currently host radar systems to detect close objects and alert drivers to other cars’ proximity and objects in their blind spots.
- *Lane detection.* In-car cameras detect lane lines and alert drivers who are drifting.
- *Infrared view.* In some Mercedes vehicles, infrared cameras detect objects ahead and display a depiction on the dashboard to alert drivers to obstructions farther on.
- *Electronic stability control.* When some cars’ computers detect skidding, they automatically apply the brakes to allow drivers to regain control. This technology is now required in all new vehicles in the United States and is already credited with saving thousands of lives.

Additional technologies in development include autonomous vehicles, which drive themselves based on computer system function rather than human operation, and are in development by automakers, software, search and mapping companies, government agencies, and universities around the world. The cars use information technologies to detect and

interpret roads and lanes, traffic lights, intersections, pedestrians, obstructions, and innumerable other factors of driving. Autonomous vehicles use cameras and 3-D imaging to recognize obstructions and foreign objects in the road, in addition to other cars, pedestrians, bicycles, and other moving objects, and predict their trajectories. This technology helps the vehicles anticipate and avoid collisions.

More than 90 percent of car collisions are determined to be caused by human error, such as distracted driving or incorrect predictions of other cars’ movement, but autonomous vehicles are expected to avoid major collisions through numerous calculations and predictions. As more autonomous vehicles take to the road, it is expected that more vehicles may fit on the road, as they will move more predictably and precisely, and eventually communicate with one another directly, thus enabling them to travel more closely together.

Several technologies powering autonomous vehicles have already been developed for the following prototypes:

- *LIDAR.* Google’s autonomous car uses a roof-mounted Light Detection and Ranging system (LIDAR), which uses spinning lasers to give the car a 360-perspective.
- *Predictive tools.* Mercedes’s car has two windshield-mounted cameras to create a 3-D image of what’s ahead and predict the objects’ movements.
- *In-wheel sensors.* Google’s car uses sensors in the wheels to detect velocity.
- *Infrastructure-based communications.* Vehicle-to-vehicle and vehicle-to-infrastructure communications use 5.9 GHz radio frequencies to communicate trajectories, proximity, and other essential driving components. Infrastructure-based communications will require major investments in infrastructure sensors and communications capabilities, which may be cost prohibitive.

Autonomous vehicles are in design around the world by major car companies and Google. Several major challenges are emerging, including regulation, liability, perception limitations, cost, and increased car use. Autonomous cars have not been legally regulated in the United States, except for burgeoning regulation in Florida, Nevada, and

California, where the cars are being tested on public roads and private tracks. Traditional regulations, such as speed limits, following-distance limits, and licensing requirements, must be adjusted for the new technologies that allow for safe travel at higher speeds, closer following distances, and unlicensed drivers. The National Highway Transportation Safety Administration is expected to release proposed rules by 2015.

Laws must also be adjusted for liability concerns; for example, if a car is speeding, is it the fault of the autonomous vehicle or its human operator? These questions abound when considering fault during incidents, among car, human operator, manufacturer, software designer, and third-party application designers.

Autonomous vehicle computers do not carry the same nuanced perception of surroundings as humans' brains do; for example, if the car is behind a stopped school bus, a human will expect children to cross the street immediately afterward, whereas a car may not have this perception. Self-driving automobiles will not be foolproof until they can "learn" from experiences.

The costs of these technologies are currently highly prohibitive for releasing the cars for mass consumption. For example, the LIDAR system costs \$70,000 per car; each technology component may raise the price of the vehicle excessively.

The increased attractiveness that autonomous vehicles would provide to driving long distances would lead to increased commute lengths, sprawl, emissions, and traffic congestion. The increased dependence on vehicles, rather than public transportation or walking in dense cities, would be detrimental to urban cores and environmental concerns.

Autonomous vehicles are expected to be launched with vehicle-to-vehicle and vehicle-to-infrastructure capabilities in 2018, with self-driving cars proliferating in 2025.

Public Transit Technologies

Transit bus fleets are typically tracked using automatic vehicle location (AVL), which gathers the locations of all buses and sends them to the management center. AVL is often a combination of GPS data-receiving technology and other, more specific, tools, such as signposts (roadside sensors that detect when a specific vehicle passes) or mobile phone network triangulation.

Inductive loop detectors, visible as rectangular outlines embedded in the asphalt of the M8 Motorway in Ireland, are used to count traffic between the towns of Cashel and Cahir, Ireland.

Though trains that operate solely above ground can use GPS data receiving systems similar to those for buses, underground trains like subways and commuter rails typically rely on track circuits. These somewhat simple tools maintain a series of circuits which, when passed over by a train, are de-energized, thereby making the system aware that a train is operating within that block. This information is relayed to a control center, which agglomerates all train locations for management of train movements. In many railroad systems, management can use automatic train control to slow or stop a train remotely in an emergency.

Aside from fleet management, a major output of bus and train tracking is passenger information systems, like countdown clocks or Internet applications that provide information to customers about the upcoming arrivals of their trains or buses. Real-time information has been demonstrated to improve the experience of transit riders and better their perception of their transit systems' operations.

Several subway systems around the world employ driverless trains through automatic train operation (ATO), which computerizes the movement of trains along a fixed route. ATO allows trains to travel closer together, since their movements are made more precise by the computerized system rather than by relying on human drivers' vision. However, most ATO-enabled subway systems retain drivers or other staff inside the train for passenger safety and emergency management. ATO results in real-time operations capabilities for transit managers and immediate information for passengers. The first partially driverless train was the London Underground's Victoria Line in 1968. Completely driverless systems are now currently being built out in Dubai and Singapore.

New innovations in transit fare payment systems have also allowed for multiple forms of payment:

Transit currency. Transit cards can be used for payment in a variety of places, including subway turnstiles, taxis, vending machines, and convenience stores. Most transit systems are moving toward a radio-frequency identification (RFID) enabled tap-to-pay system, while older models still require the swipe of a card.

City cards. Some cities, particularly in Europe, have launched highly successful cards used to pay for transit but also grant access to other city services, like public Wi-Fi, bicycle rentals, and libraries.

Mobile phones. Technologies being developed to enhance payments through mobile phones—including Google Wallet, Square, PayPal, and banking apps—make it possible to collect fare payments quickly and without requiring intricate internal systems for collection.

Open payment. The United States is experiencing a growing push to deploy open payment standards that allow any bank card or mobile device to be used for payment. These systems offer flexibility for future technological innovations but may limit future financial and business innovations by transit agencies.

Pedestrian navigation in cities is an area of increasing importance in technology development, as smart phones proliferate and users demand accurate, real-time wayfinding information to direct

them to their destinations. Using GPS data and cell phone tower triangulation, smart phones detect the locations of their users and provide walking, transit, and driving directions to their destinations. These smart phones have improved to provide spoken directions to users who are visually impaired, and interact with local landmarks to offer information and store discounts.

Inland Waterways, Freight Traffic and

Today, inland waterways are multifunctional, offering a variety of commercial and recreational uses as well as nature conservation opportunities.

Traditionally built for navigation and transportation, the introduction of rail and road haulage in many countries led to a downturn of water transportation and, with it, the inevitable but mostly reversible deterioration of the engineering, architectural, and landscape amenities associated with these routes. However, the increasing importance of securing sustainable development and green growth is leading to a revival in water transportation via inland waterways.

History

The earliest inland waterways, or canals, were created for the purpose of irrigation rather than for navigation. The first known example of a canal to improve the natural course of a river was the series of five canals that Pharaoh Pepi I built near the First Cataract of the Nile River ca. 2300–2180 B.C.E. The Phoenicians, Assyrians, Sumerians, Persians, and Egyptians all built various types of canals. The Chinese began a series of canals between the third and first centuries B.C.E., including one that joined two separate waterways, the Xiang and Lijing Rivers. This was the first contour transport canal and was devised for the transportation of military supplies.

In Europe, the Romans built canals in France, Italy, the Netherlands, and Britain, also for the purpose of transporting military materiel but mainly for irrigation. Through the use of rivers it was possible to extend seaborne trade many miles inland. The Romans built a canal at the mouth of the river Rhine to create passage for Mediterranean shipping. Following the collapse of the Roman Empire, inland waterways in Europe fell into disuse until commercial expansion in the 12th century saw a resurgence in river use and artificial waterway development. Rivers often provided the means for European explorers, traders, conquerors, or settlers, arriving in Africa, Asia, and the Americas by sea, to enter the interior of those continents. In many places, ports arose not only at the mouths of rivers but also at the so-called head of navigation, the highest point up a river that seagoing ships could reach into the interior. Examples of such ports include London and Calcutta.

A vast program of building, including monasteries, castles, and churches, took place in the Middle Ages, which led to further improvements of rivers for transportation of building materials. At the onset of the Industrial Revolution (ca. 1750–1850)

the network of land-based transportation was unsatisfactory, with the system consisting of either coastal shipping with its restrictions or horses and carts, which were unable to carry more than one or two tons of cargo at one time. This meant that the supply of commodities now in high demand—for example, coal and iron ore—was limited, keeping prices high and suppressing economic growth. The modern canal system in Europe was mainly a product of the Industrial Revolution as demand rose for a faster, economic, and reliable way to transport goods and commodities in bulk. It was private individuals, industrialists and prospectors, who were responsible for improving inland waterways and the development of the systems in Europe.

For example, the potter Josiah Wedgwood invested in canals, transporting the clay to his factory doors and his finished goods to market in Manchester, Birmingham, and farther away by water. By the height of “canal mania” there were over 4,000 miles of navigable inland waterways in Britain.

The new canals were built with a towpath alongside the canal for the horse to walk along. One horse was capable of pulling up to 30 tons at one time. Horse-drawn canal boats continued to be used, particularly in Britain, until the late 1950s, when they were replaced with steam- and diesel-powered boats. In Britain, an act of Parliament was required to authorize the construction of each new canal. Rival canal companies were formed and competed for canal construction in an area.

Canal-owning companies did not own or run a fleet of boats. They charged private operators tolls to use the canal. From these tolls they would try, with varying degrees of success, to maintain the canal and pay back initial loans. The boats used on canals were a mixed bunch, including flyers that carried light cargo and passengers at relatively high speed day or night and a variety of river craft. The main method of transportation on the canal system was the narrow boat or barge. These were owned and operated by individual carriers or by carrying companies.

Canals were built under constraints of engineering technology and finance. For these reasons the inland waterways constructed were often narrow in width and the standard dimensions of canal locks were 72 feet 7 inches (22.1 meters) long by 7 feet 6 inches (2.3 meters) wide. This limited the size of the boats capable of using these waterways

and limited the quantity of cargo they could carry. These factors ultimately led to the demise of inland waterways in Britain.

Decline and Conservation

By the mid-19th century railways began to threaten inland waterways. Railways could carry greater loads than canals; they could transport more people and move people and goods more quickly. In order to compete, canal companies were forced to cut their prices, reducing their profits and leading to reduced investment in the canals. By the latter part of the 19th century, rail companies began buying out struggling canal companies in Britain. Where canal companies resisted successfully, the pressure from rail transportation was in areas where the canals occupied niches in transport markets that the railways were not able to access, including supplying local markets, factories, and mills.

Parts of continental Europe, however, were proactive in protecting their inland waterways, making them more resilient to progress. France, Germany, and the Netherlands modernized their canal systems drastically between 1876 and 1899, widening them to allow larger boats, often capable of transporting up to 2,000 tons, to navigate along them. These waterways still offer an economically viable and competitive way of transporting freight. Most major industries in Britain that generate bulk transport needs today are sited on the coast. Although they cannot enjoy direct access to inland waterways nationally, they do take advantage of the waterways in other European countries by use of modern river-sea ships and modern barges.

In Britain, the canal system was nationalized in 1948 under the British Transport Commission. Freight transport declined rapidly in the 1950s and 1960s with mass road transport, and increasingly, canals were abandoned due to falling traffic. In 1963 the decision was made to formally cease commercial carrying on the canals. However, recreational use of canals in Britain has steadily increased as people's leisure time and disposable income increased. The social, economic, and environmental benefits of inland waterways is once again being recognized. Inland waterways are being valued as part of Britain's landscape, the need to protect and the ability to enjoy their industrial heritage and archaeology, for their contribution to urban landscapes and the unique habitats and ecosystems they support, and

for the varied leisure and recreational activities they offer. As a result of this, the Inland Waterways Association (IWA) was formed. The IWA advocates the restoration, conservation, maintenance, and sensitive development of the inland waterways of England and Wales and promotes the use of inland waterways for recreational and commercial purposes.

United States

There are more than 12,000 miles of inland and intracoastal waterways in the United States. These waterways are found in 38 states and handle approximately half of all inland waterway freight (or one-twelfth of all national freight). According to the U.S. Army Corps of Engineers (the Corps), which is responsible for the operation and maintenance of these waterways as part of its civil works program, the network transports around 600 million tons of domestic cargo movements every year. Commodities shipped in the United States via inland waterways include petroleum and petroleum products (approximately 310 million tons), coal, food and farm products, chemicals, aggregates, machinery, and equipment.

The inland waterway system developed gradually throughout the nation's history and predates the founding of the nation itself. Before the onset of rail and highway transport, inland waterways were a primary means of transporting bulk goods. Early canals were followed by river improvements, such as clearing obstructions and dredging, which provided a safer channel for commercial navigation but were still subject to extreme variations in water levels. Locks and dams were constructed to raise water levels and provide a more reliable channel on rivers such as the Ohio, the Illinois, the Upper Mississippi, and the Tennessee. Through the early 1800s, inland waterway development was left to the states, until the U.S. Supreme Court affirmed the constitutional federal authority over interstate commerce in 1824. Shortly thereafter, the federal government began to provide funding and support to these waterways to improve interstate and international commerce.

The Corps is responsible for navigation channels, harbors, locks, and dams, and it maintains and regulates channel depths through dredging and water management. Costs for maintenance and construction of inland waterways are funded

A barge transporting cargo under the Fremont Bridge, which carries an interstate highway over the Willamette River in Portland, Oregon. The 12,000 miles of U.S. inland and intracoastal waterways help transport as much as 600 million tons of cargo around the country every year. With an overall 13 percent rise in ships arriving at U.S. ports in 2010, the United States anticipates growth in inland waterway freight traffic that may strain the antiquated infrastructure of existing canals and locks.

by the Corps through appropriations and by the commercial user industry through user fees paid to the federal government. The Corps pays 100 percent of the cost for studies and for operations and maintenance on the inland waterway system, while the Water Resources Development Act 1986 provided that expenditures for construction and major rehabilitation projects on inland waterways are to be cost-shared on a 50/50 basis between the federal government and users through the Inland Waterways Trust Fund (IWTF).

Congress is faced with competing proposals relating to future financing for inland waterways. Improvements in rail and highways have decreased reliance on inland waterways as a means of commercial freight transportation, although this situation is expected to change. The Department of Transportation's "Freight Analysis Framework" (2007) has forecast a 70 percent increase in freight traffic by 2020. Highways, railways, and waterways will all be impacted. Waterways pose an efficient and sustainable mode through which to manage this

increase, particularly when considering the benefits associated with water transportation. However, the United States is faced with significant cost implications to get the inland waterways up to speed due to their age and lack of investment and maintenance; presently, the 50-year-old federal locks still operating are at the end of their expected life span, reducing reliability and capacity in the inland waterway infrastructure.

In addition, with the number of ships calling at U.S. ports rising by 13 percent in 2010, the pressure on U.S. inland waterways is set to increase. A report indicates that following the completion of the expansion to the Panama Canal to accommodate 366-meter-long ships with a 15-meter draft, the canal will make it easier for Asian ships to reach America's East and Gulf Coasts. The forecasted increases in shipping are considered to offer an efficient mode of transport, with a single barge having the equivalent dry-cargo capacity of 16 railcars or 70 trucks and the liquid-cargo capacity of 46 railcars or 144 trucks.

Other International Examples

Other countries seeing a rise in volumes of cargo transported by inland waterways include China, India, and the countries of southern and eastern Africa, all of which benefit from considerable lengths of navigable rivers.

China's inland waterway network is the largest in the world. It has a navigable length of 123,495 kilometers and consists of over 5,000 rivers and tributaries. In 2007 China's inland waterways transported 1,180 million tons of cargo, compared with waterway cargo of 800 million tons in the United States and 500 million tons in the European Union. The Yangtze River is the largest waterway with the Pearl River and Hangzhou-Beijing (known as the Grand Canal) waterways. The Pearl River Waterway is an important transportation link between Hong Kong and the manufacturing areas of Guangdong, while the Grand Canal is the longest human-made waterway in the world, extending 1,743 kilometers.

In India there are 14,500 kilometers of navigable waterways. The Inland Waterways Authority of India (IWAI) was established in 1986 under the Inland Waterways Authority of India Act of 1985 for the development and regulation of inland waterways for shipping and navigation. It is responsible only for the declared National Waterways, of which, there are five. The IWAI undertakes projects for development and maintenance of waterways infrastructure on national waterways using a grant received from the Ministry of Shipping. Data on cargo movements in India indicates a more than 100 percent increase in the volume of goods transported by inland waterways between 2003 and 2010.

The Community of Eastern and Southern African States (COMESA) has resolved to revive inland waterway transport and increase trade between the countries, bringing them together. This has led to an expansion of trade between COMESA countries from \$3.1 billion in 2000 to nearly \$9 billion in 2007. The Great River Nile Co., founded by Captain Abdelkader Saeed, proposes the use of the river Nile in inland cargo movement. Door-to-door services are included in the project, which would incorporate inland road transport links only between seaports and river docks. This project would reduce transportation costs and time and relieve burdens on roads, as well as reduce emissions of greenhouse gases.

Conclusion

It appears that the development of inland waterways as a viable mode of freight transportation is being reinvigorated. Long-standing waterways are being modernized to accommodate the larger modern water barges and ships; this is illustrated by the engineering changes to the Panama Canal and the proposed changes to the Suez Canal (which connects the Nile and the Mediterranean Sea with the Red Sea), which today supports 8 percent of the world's shipping traffic. While reviving and improving the canal network in Britain is less likely, the U.S. Congress is in a position to ensure that the protection and improvement of the inland waterway system enables the network to compete alongside rail and road haulage as freight volumes increase.

There are a number of advantages to using inland waterways and barge transportation that should not be overlooked, particularly in the age of austerity and green growth. Barges emit less greenhouse gases and use less fuel, which lowers transportation costs. Transportation and travel by inland waterways causes fewer deaths and creates less noise and other nuisances due to their location away from human settlements. Even where canals need to be widened or restored, research in Germany has shown that of total external environmental costs of the various freight transport modes, water transport has much lower environmental costs.

Inland Waterways, Operations and Management

The U.S. inland and intracoastal waterway system is not as well-known as its airway, railway, or highway networks, but inland waterways are an essential and often overlooked part of America's freight transportation system, handling approximately 600 million tons and 300 billion ton miles of domestic cargo shipments per year. Inland waterways are the primary artery for more than half of the nation's grain and oilseed exports, for about 20 percent of the coal for utility plants, and for about 22 percent of domestic petroleum. Most of the cargo is raw materials and liquid and bulk cargo such as coal, petroleum, chemicals, grain, processed metals, food, farm products, and cement, sand, and gravel. The U.S. Army Corps of Engineers (USACE) has overseen and maintained the waterways since the 19th century, but in the 21st century, politics and special interest groups as well as economic pressures have affected the oversight and modernization of the inland waterways.

Demand for freight transportation in America is escalating. The U.S. Department of Transportation's "Freight Analysis Framework" report forecasts a 70 percent increase in freight traffic by 2020. Traffic on inland waterways is forecasted to increase by 51 million tons of freight from 2012 to 2020, and by 2040, the increase is expected to exceed 118 million tons. This growth will challenge the capabilities of all transportation systems, especially highways, but it will also impact rail and water transportation. The marine ports system is especially important for

America's international trade, valued at more than \$944 billion in imports arriving in the United States by water. America depends heavily on waterborne trade for its growing export markets, especially agricultural products, manufactured goods, and energy and refined petroleum products. Even if growth slows worldwide and Europe continues to undergo economic problems, U.S. trade with Asia and Latin America and growth forecasts require major investments in U.S. marine ports and waterways.

History

As early in American history as 1797, George Washington and Benjamin Franklin recognized the importance of waterways in developing the country. The portal canal at the Great Falls on the lower Susquehanna River was the first working canal in Pennsylvania and one of the first in the new country. Then, as America expanded so did its canal system, supported by river improvements like clearing obstructions and dredging safer channels. Private and public companies constructed a system of locks and dams on the Ohio, Illinois, Mississippi, and Tennessee Rivers and many of their tributaries.

President Thomas Jefferson authorized a Corps of Engineers to be stationed at West Point on March 16, 1802, an act that led to the creation of the modern U.S. Army Corps of Engineers (though the organization had existed since 1775). The General Survey Act of 1824 authorized the use of Army engineers to survey road and canal routes, and in the same year, Congress passed legislation to remove sand bars from the Ohio River and snags on the Mississippi and assigned that responsibility to the Corps of Engineers. Today, the USACE manages America's more than 25,000 miles of inland waterways and the 12,000 miles of commercially important waters.

Maintenance and Repair

The inland waterway system is aging, with the average age of its 192 commercially active locks now over 50 years old. Many of the functioning locks and dams were built in the 1930s, including a majority of the locks on the Upper Mississippi, Illinois, and Tennessee Rivers, and they need modernization or major rehabilitation. Even the "second generation" Ohio River higher lift locks and dams were built in the 1950s. Older structures like the George Washington and the San Francisco–Oakland Bay Bridges can enjoy a long traffic life as long as they

are maintained, rehabilitated, and modernized, but the USACE reports that in dollar terms, funding for inland waterways infrastructure has been flat or declining for decades even as the structures age.

Commercial towboats pushing barges lashed together as tows make up the majority of the inland waterway traffic. Each barge has a capacity of 1,400 to 1,800 tons of cargo, and a single 15-barge tow carries the freight car equivalent of 870 tractor trailer trucks, creating an inexpensive and fuel efficient method of freight hauling especially suited to bulk cargo that is not time sensitive. Lock and tow size and condition are critical factors in determining the amount of cargo that can pass through a lock over a set amount of time. Many modern tows operate with 12 or more barges passing through a 600-foot lock, requiring the tow to be divided into two sections to pass the lock, which can be time consuming and cause long lines of tows waiting to move through the lock.

The USACE began to modernize the locks on the Ohio River in the 1960s, adding 1,200-foot chambers that can pass a typical tow in a single lockage. In the decades since the 1960s, the Corps of Engineers has constructed a new dam with twin 1,200-foot locks at Olmsted, Illinois, at the juncture of the Ohio and Mississippi Rivers, and a second 1,200-foot chamber at McAlpine Locks and Dam near Louisville, Kentucky, as well as the Kentucky Lock on the Tennessee River and the Inner Harbor Lock on the Gulf Intracoastal Waterway at New Orleans, Louisiana. The Corps also has ongoing projects in other states and several major rehabilitation projects, including modern navigation facilities and investment in environmental restoration and management. These projects represent an investment of over \$3.5 billion in inland water modernization over the next decade.

There are several key navigation improvement feasibility studies of the current inland waterway system, including one of the Upper Mississippi River and Illinois Waterway, the Ohio River, the Gulf Intracoastal Waterway, the Black Warrior River, and the Tennessee River, which are expected to pinpoint navigational and environmental actions necessary to support the inland waterway system.

Lock Performance and Competitiveness

The lack of adequate funding has changed the nature of maintenance programs from preventive

maintenance to a fix-as-fail policy. A lock malfunction taking weeks to fix can produce major consequences for barge traffic and for manufacturers dependent on receiving their cargo in a timely fashion. Contrasted with the decline in civil works investment, the USACE reports an increase in the backlog of needed maintenance and repair of individual projects. As funds have dried up, the Corps has been addressing only the most urgent maintenance and repair projects and postponing the others, estimating that more than half of the repairs were navigational.

Lock performance data from the Lock Performance Monitoring System of the Corps of Engineers indicates that lock down time has more than doubled over the past decade and data for locks on the Upper Mississippi River suggests that increasing time for unscheduled lock maintenance and mechanical malfunctions are the main reasons for the unavailability of locks. In 2009, about 90 percent of locks and dams on America's inland waterway system experienced unscheduled delays. Maintaining existing levels of lock operation will cost \$13 billion in total investment needs by 2020, and an additional \$28 billion by 2040. Current funding levels can support only \$7 billion by 2020, and an additional \$16 billion by 2020. About 27 percent of these needs involve constructing new lock and dam facilities.

Continuous unavailability of locks will seriously impact the viability of the inland waterway system for freight transportation as shippers concerned over lock unavailability, unreliability, and system integrity may decide to ship by rail or highway. On a system-wide basis, waterways are generally more energy efficient and produce fewer air emissions than land freight, which provides the rationale and national interest for preserving them. Current fiscal and maintenance policies may seriously impact the future of the inland waterway system.

America's manufacturers are able to ship goods efficiently throughout the country and export them overseas to keep the country competitive because of a diversified transportation network operating on land, sea, and air. The transportation cost savings from inland waterways shipping is estimated to exceed \$7 billion annually compared to the cost of shipping by other methods. Frequent planned or unplanned closing of aging locks because of mechanical failure or regularly scheduled maintenance on the inland navigation system create costly

delays and contribute to the further deterioration of the system.

Economics of Maintenance

Although economic factors motivate many port authorities simply to maintain their existing conditions to fulfill customer needs and requirements, they are compelled to plan improvements as well. They project spending a combined \$18 billion through 2016 on infrastructure improvements for water terminals while their private sector terminal partners anticipate spending a combined \$27.6 billion for a total of nearly \$46 billion.

Accommodating the massive new Panamax cargo ships that will ply the enlarged Panama and Suez Canals will be a major challenge for U.S. ports, especially those on the East Coast. To meet anticipated growth in trade and domestic waterborne traffic, public investment will need to be more than \$30 billion dollars by 2020. This includes navigational dredging and operation and maintenance needs for both marine dredging and inland waterways and marine ports, but the figure doesn't include private sector investments to improve the port facilities themselves or the connections to roads and rail systems to reduce traffic congestion caused by trucks entering and leaving port facilities.

Funding needs are expected to reach \$92 billion by 2040, which will leave the United States with a funding gap of nearly \$46 billion based on current investment trends and the USACE annual budget. More than 61 percent of the identified need and funding gap is intended for marine navigation and operations and maintenance, and about 39 percent for inland waterways.

The U.S. economy depends on low export transportation costs to offset higher wage levels and production costs compared with its competitors. Expensive export costs for goods will affect the competitiveness of the United States in global markets. This is already happening in a small number of industrial sectors and could worsen in the future.

USACE Inland Waterway Study

The 2008 USACE publication, "Great Lakes and Ohio River Navigation Systems Commerce Report," notes that of the more than 25,000 miles of inland, intracoastal and coastal waterways, the federal government improves and maintains almost 11,000 miles, or about 45 percent of the total channel

length, including dredging and installing and maintain navigation structures like locks, dams, dikes, and revetments.

Federal and state governments and port authorities and carriers share responsibility for the nation's waterway transportation system. The inland waterway transportation industry features extensive cooperation and coordination between public and private sectors and the USACE facilitates the waterway navigation projects that ensure safe passage for vessels.

The USACE Institute for Water Resources prepared a study titled *Waterways Modernization: Preparing for Post-Panamax Vessels*, which used in-house specialists, visiting scholars, and experts in deep draft navigation and inland navigation districts. The study provided advice for Congress on how to address the critical need for additional port and inland waterway modernization to accommodate post-Panamax vessels when the Third Set of Locks Project to double the capacity of the Panama Canal is finished in 2015. Marine experts are certain that the Panamax vessels will shape the direction of intermodal freight logistics in the United States, especially in trade flows, ship sizes, volumes, transshipment port development, and in which U.S. ports will benefit by the new locks. The timing and scope of these future logistics depend on present actions and legislation.

Financing the Inland Waterway System

Since inland waterways are an important part of America's transportation and economic system, the federal government has invested in navigation infrastructure since its creation, and has supported commercial barge shippers and other waterway users by funding operational costs, capital expenditures, and major rehabilitation projects on inland waterways.

Inland waterway users are not charged tolls, but since 1978 the Inland Waterways Act has imposed a barge fuel tax on commercial users to maintain and improve waterway structures and facilities. The act also established the Inland Waterways Trust Fund (IWTF), appointing the U.S. Treasury to hold the funds, which are used to cover half the cost of new construction and major rehabilitation of the inland waterways infrastructure. In 1980, the barge fuel tax was set at 4 cents a gallon but was gradually raised to 10 cents per gallon by 1986.

The Water Resources Development Act of 1986, a wide-ranging bill concerning waterway transportation, established the Inland Waterways Users Board to recommend construction and rehabilitation priorities and spending rules for the inland waterways. It established a 50/50 cost shared basis for projects between the federal government and commercial users and fixed federal government responsibility for operations and maintenance costs at 100 percent. It also gradually increased the fuel tax to 20 cents a gallon by 1995.

The inland waterway system faces an uncertain funding future. The fund's balance has declined significantly since 2005 for reasons that include increased appropriations, cost overruns, and decreased revenues. If the current financing system is not changed, IWTF spending will have to be curtailed. The USACE estimates that by 2020, maintaining the current levels of unscheduled delays on inland waterways without making them worse will require more than \$13 billion, with current funding levels expected to reach just \$7 billion. About 27 percent of these projects involve constructing new lock and dam facilities and 73 percent are needed to rehabilitate current facilities.

The time needed to complete USACE projects drives up the cost and creates a project backlog because declining tax revenues have created a stagnant funding scenario for the Corps. If funding levels continue to decline, the Corps estimates that 22 major construction and rehabilitation projects will not be complete until 2090. In recent years, a trend toward cost overruns and project delays have been important factors in the decline in the IWTF. The Corps acknowledges that it needs to create a new national strategy.

Investment in Inland Waterways

In a 2009 report, the American Society of Civil Engineers (ASCE) concluded that America's infrastructure is close to failing and called on the president and Congress to adopt a long-term, systematic approach to improve its condition and performance. ASCE found that 47 percent of all locks that the USACE maintains were classified as functionally obsolete in 2006. If there are no new locks built within the next two decades, another 93 existing locks will be obsolete by 2020. As waterway use increases and the current system continues to age, with many locks beyond their design life of 50

years, the deteriorating condition of the system will impede recovery from natural or manmade disasters and threaten the American economy.

The ASCE stressed that America's inland waterways are strategic economic and military resources because they are capable of moving large amounts of cargo. The U.S. Army War College contends that the strategic contributions of these inland waterways are not well understood and this lack of understanding affects decisions about their management, funding, and integration with other national transportation systems. A better understanding of the inland waterway system will help build an effective transportation network for the 21st century.

Government Plans

The George W. Bush Administration proposed a plan to phase out the inland waterway barge fuel tax and institute a lock fee resembling a toll, and the Obama Administration recommended replacing the fuel tax with user fees that would have increased revenues and mandated more spending on inland waterways projects in fiscal years 2010 through 2013 and fiscal year 2014. Congress and industry interests rejected each of the proposals. The National Association of Manufacturers (NAM) opposed both Bush and Obama administration traffic proposals on the grounds that a new fee will lessen the competitiveness of the inland waterway transportation system and negatively impact the major industrial and agricultural waterway shippers using the Upper Mississippi, Ohio, Illinois, and other rivers.

Acknowledging that the present system of locks and dams requires billions of dollars in increased investment, the NAM also pointed out that no long-term capital plan to guide system-wide investments exists. Inland waterway projects currently take from 10 to more than 20 years to complete, an unnecessarily long time period that increases construction costs and adds delays to the system. Projects routinely experiencing cost overruns averaging almost 120 percent more than Congressional revenue authorizations are also unsustainable.

In April 2010, the Inland Waterways Users Board, (IWUB), a committee advising the USACE on inland waterways, endorsed an alternative proposal that many barge industry interests support. The plan prioritized completion of navigation projects across the system, sought to improve the

government's management and delivery of projects to help control costs, and recommended an increase in the diesel fuel tax from 20 to 29 cents a gallon to help finish 25 projects in the next 20 years. It also recommended that federal and local authorities continue equally sharing the cost for projects totaling more than \$100 million but suggested that the federal government cover the full project costs for new dams and rehabilitation projects costing less than a \$100 million. The board estimated that its plan would provide \$7.6 billion in new revenues over 20 years. NAM recommended that Congress support implementation of the plan in the Water Resources Development Act authorization.

The barge industry and agricultural groups argue that the changes are necessary to bolster the trust fund, improve deteriorating infrastructure, and distribute costs of the waterway system more equitably. The Obama administration agreed that waterway infrastructure systems need to be upgraded but favored higher user fees instead of shifting the costs to the federal government. Some taxpayer and environmental groups favor increasing non-federal costs and not just construction costs but also operation and maintenance expenses that are not currently shared.

The Water Resources Development Act

The USACE planned and developed the Water Resources Development Act (WRDA), a biennial legislative package that is the means for water projects to be studied, planned, and developed. Passed for the first time in 1974, it is also the legislative vehicle for implementing policy changes in the water resource projects and programs that the Corps has undertaken.

The Water Resources Development Act of 2013 would authorize the project delivery recommendations of the Obama administration proposal, but it would not change the existing fuel tax or cost sharing arrangement. The Obama administration's fiscal year 2014 budget also proposed a new, unspecified user fee expected for inland waterways. As it considers inland waterways legislation, Congress may debate the appropriate cost sharing between the federal government and waterway users for various inland waterways costs, the appropriate user fee to fund the nonfederal share, including fuel taxes and lockage fees, and the preferred planning process and funding levels for inland waterways.

The current WRDA bill has sparked controversy from both Democratic and Republican legislators. Its provisions include effectively requiring a tripling of the amount that the federal government spends for harbor maintenance and related work, which would mean a \$15 billion increase in spending over the next 10 years. It would eliminate cost sharing for maintaining channels deeper than 45 feet, a key provision in the Water Resources Development Act of 1986, and expand the federal role in other areas that previously had always been nonfederal responsibilities. The bill also would establish an annual per vessel fee to raise \$1.1 billion in additional revenue over 10 years from commercial users of inland waterways.

Inland Waterways, Passenger Traffic and

Ferries are boats and ships that carry passengers, cargo, or vehicles across a body of water, and generally operate on a regular schedule ferrying back and forth for a portion of the day. In some cases a ferry may be the primary or only means of transport between two points and constitute part of the public transportation system, as in many island communities and cities on the water.

In New Orleans, ferry service has been part of the transportation system since 1823, predating the streetcar system by 12 years. New Orleans is located at a bend in the Mississippi River and is bordered by two lakes, Lake Pontchartrain in the north and Lake Borgne in the east. Ferries were used to transport passengers and goods back and forth between the East and West Banks of the Mississippi River, with a regular ferry schedule established in 1827 between Canal Street (just outside what is now known as the French Quarter) and Algiers, the community on the West Bank. Today this is one of the oldest operating ferries in the country. More ferries were added in subsequent decades as the city spread out along the riverbanks. A railroad ferry added in the 1850s became obsolete with the construction of the Huey P. Long Bridge, a railroad and vehicular bridge across the river, built in 1935. Private ferry service declined in the 20th century after the Greater New Orleans (GNO) Bridge was built, providing another vehicular bridge across the Mississippi.

The GNO was operated by the Mississippi River Bridge Authority, which acquired the main public ferry lines in the area—the Algiers Ferry, the Gretna Ferry, and the Chalmette Ferry, which connects two state highways. Control of the ferries

was later passed to the Crescent City Connection Division of the Louisiana Department of Transportation and Development. Tolls of \$1 per automobile are charged, but only from the West Bank to the East Bank. Westward trips, as well as all trips for bicycles and pedestrians, are free. Today, New Orleans has the busiest ferry system in the country outside of Washington State and New York City, with most passengers using it as part of their daily commute.

A number of ferry services operate in the New York City area. New York Water Taxi offers commuter service along the East and Hudson Rivers. Seastreak offers commuter ferries from Monmouth County, New Jersey, to Manhattan, as well as service to some of the home games at Yankee Stadium and weekend service to Martha's Vineyard. The New York Beach Ferry operates weekend and holiday service to Rockaway Beach in the summer. There are also several companies offering sightseeing ferry trips in the city area.

The largest ferry operation in the country is the Staten Island Ferry, with a daily ridership of about 75,000. Ferry service between Staten Island and southern Manhattan began in the 18th century, with individual sailors transporting passengers on two-masted sailboats. Motorized ferry service was offered in the 19th century by steam engine tycoon Cornelius Vanderbilt, and city government assumed control of the ferry service in 1901 after a ferry collision left five dead. Operated by the New York City Department of Transportation, the Staten Island Ferry consists of eight vessels ferrying back and forth between Staten Island and Manhattan. The ferry runs 24 hours a day, 365 days a year, and carries only passengers and bicycles, for free. Until stricter transportation security regulations were enacted following the September 11, 2001, terrorist attacks, the ferry also transported vehicles for a \$3 toll. Commuter parking is available at the Staten Island terminal. In the past, the ferry charged for passengers, though it was always cheap—in 1975, the fare was a quarter, less than half of the city's cost to operate it. The fare increased to 50 cents in 1990, but since 1997 no fare has been charged.

Though primarily operated for the sake of commuters, the Staten Island Ferry is a popular tourist attraction because of its view of the Statue of Liberty and the Manhattan skyline at night. It has become one of the icons of the city, appearing in the

The New York Waterway company's East River Ferry is underway near the Manhattan Bridge in New York City, July 2013. It is one of a large number of ferry services operating in New York City and its surrounding waterways.

opening credits of David Letterman's nightly television talk show, in the Melanie Griffith film *Working Girl*, and in the opening montage of Woody Allen's film *Manhattan*. The Staten Island terminal does not connect to commuter rails to other boroughs, though connections may be made by first taking a Staten Island bus.

In Washington State, the Pacific Northwest state's unique geography has made ferries indispensable. Numerous inland waterways run through the Puget Sound area, which has a number of inhabited islands and peninsulas. The waterways played a major role in the settling of the area, providing natural transportation routes, and steamships began operating in the Sound in the 1830s, before the town of Olympia had even been founded. By the end of the 19th century there were 40 steamboat routes on the Sound, most of them operated by

a boat purpose-built for it. The "mosquito fleet," as it was called, dwindled in the 20th century as automobiles became common.

Today, many of the ferries serving Puget Sound and the San Juan Islands are operated by Washington State Ferries (WSF), the largest ferry fleet in the country and third largest in the world. Owned and operated by the Washington State Department of Transportation, WSF transports 11 million vehicles a year, more than any other ferry system in the world. It grew out of the state's purchase of the fleet of the Black Ball Line, one of the operators of the old "mosquito fleet." It consists today of 22 ferries carrying people and automobiles, on eight routes that are legally part of the state highway system, though most have no traversable road component.

Washington includes numerous other ferry services, including the Guemes Island Ferry, the Wahkiakum County Ferry, the Gifford-Inchelium Ferry, the Steilacoom-Anderson Island Ferry, a Washington State Department of Corrections Ferry for service to the McNeil Island Corrections Center, the Hat Island Ferry, and many private ferry services for island residents.

Other major ferry services in the United States include the ferry fleets in San Francisco, serving tourists and commuters in the Bay Area, and the Alaska Marine Highway System, which operates among the Aleutian Islands and the Inside Passage of Alaska, as well as providing transportation to and from neighboring British Columbia, Canada. Part of the National Highway System, the Marine Highway System is state and federally funded. Mainland routes provide service to Bellingham, Washington, providing some of the limited transportation of vehicles from Alaska to the lower 48 states without passing through Canada or requiring a passport.

Inland Waterways, Planning and

The U.S. inland waterways system is a valuable component of the national transportation system, transporting bulk freight commodities such as coal, corn and wheat, oil and oil products, heavy manufactured goods, and aggregates. The contribution of waterborne transportation to the national economy is expected to grow significantly over the coming decades. The inland waterways system consists of two principal types of waterways: the Western River system, composed of the Mississippi River system and the Columbia–Snake river systems, and the intracoastal waterways adjacent to the Gulf and East Coasts. In total, the United States has over 12,000 miles of commercially navigable rivers and intracoastal waterways, serviced by 192 commercially active locks and their associated dams.

U.S. Army Corps of Engineers

Inland waterways transportation infrastructure is unique in that it is almost exclusively federally regulated, constructed, and maintained. The U.S. Army Corps of Engineers (USACE) serves as the primary manager of river navigation infrastructure in the United States, having responsibility for lock and dam construction and maintenance, channel dredging, and reservoir pool maintenance. The federal government operates and maintains 185 of the navigational locks on the inland waterways system.

Management of the system is both costly and complex. The USACE is required to maintain a proper water level and ensure that river systems, such as the Mississippi River, the Ohio River, and the Columbia–Snake Rivers and their respective major tributaries, are navigable under all weather

and river conditions. In addition to overseeing the building and maintenance of dams and locks, the USACE dredges channels to a navigable depth and deepens coastal and inland ports to accommodate commercial vessels.

The number, size, and placement of lock and dam infrastructure can impact the type of commodities being shipped on the waterways. Locks vary in length between 600 feet and 1,200 feet. The larger locks, being able to handle more barges, expedite the speed with which tows can transit a lock by reducing waiting times at locks.

The sizes of tows vary depending on the physical characteristics of the river, the number of locks, and the lock chamber size. For instance, the Ohio River can handle tows with 15 barges, while the Lower Mississippi River has no locks and can accommodate tows of 40 or more barges. Smaller tributaries, such as the Arkansas River, have conditions that greatly limit the size of tows. North of St. Louis, the Upper Mississippi River has many locks, which can accommodate only smaller tows, requiring barges to break tows into smaller groups to allow safe passage through the locks. Another consequence of this geography of lock and dam systems is that most manufactured products, shipped via container-on-barge, are not shipped north of the Port of Memphis. Sections of the Western River system with a high number of lock and dam infrastructure better accommodate the shipping of large bulk commodities, such as coal, aggregate, grain, and fertilizers.

As an agency within the Department of Defense, USACE is funded by the federal government and performs its duties as authorized by Congress. In addition to providing efficient navigation, the federally maintained waterways infrastructure facilitates other uses of water resources, including drinking water, irrigation, flood control, recreation, and fisheries.

Infrastructure and Funding Crisis

The inland waterways infrastructure of dams, locks, and channels is aging. Many of the locks and dams are between 50 and 75 years old and in need of repair or replacement. There is a need for regular and intensive maintenance for many of these locks to fend off a system failure. Given the expected expansion of waterborne commerce on the system—more than 20 percent by

2030—many of the locks are in need of expansion in order to accommodate and expedite the movement of large tows.

Due in part to the long and successful history of the infrastructure built and maintained by the USACE, the public tends to take for granted the positive contributions of the inland waterways and underestimates the level of resources required to maintain lock and dam infrastructure. Beyond transport, the inland waterways and reservoirs operated and maintained by the USACE provide a broad range of benefits to a variety of users. The occasional disruptions to these benefits, such as lock closings and flooding, tend to focus public attention on the benefits of the inland waterways infrastructure. Even relatively minor disruptions—such as problems that require the lowering of water levels of rivers, reservoirs, and lakes—can remind people of the importance of the infrastructure. Individuals and businesses that rely on the waterways systems' value for transport, water supply, and recreation, often take note during severe low-water events.

Lock failures have the potential to wreak devastating impacts on industries reliant on waterborne transportation for dependable delivery. The failure or structural compromise of a USACE-managed infrastructure component or the closing of a navigable waterway could result in many economic impacts to both the public and commercial sectors. For example, a lock failure could interrupt or curtail commodity movements across a broad section of the system and have dire local impacts as commodities are transferred to other transportation modes; industrial customers lose access to inputs and commercial customers lose access to finish products. Secondary impacts could also multiply quickly: employment may drop, traffic congestion and highway impacts may increase, and even industries farther away may be impacted by a shortage of inputs or higher priced inputs.

The economic impact of a disruption in the inland waterways transportation system becomes even more costly when the nature of the primary waterborne commodities is considered. The economic ripple effect for infrastructure failure is especially notable for commodities such as coal, used in the many power plants adjacent to rivers to generate low-cost electricity, and staple grains such as wheat and corn. Most coal-fired power plants maintain

a 60-to-90-day supply of coal; however, long service disruptions in lock infrastructure could likely lead to very high spikes in electricity cost within a region. High food prices would also be likely, as many crops and agricultural inputs, such as fertilizers, are shipped via barge.

Cost of Modernizing and Repairing

The infrastructure needs of the system over the next 20 years were recently studied by the Inland Waterway Users Board, comprising a key set of waterways stakeholders. Authorized by Congress in the Water Resources Development Act of 1986, the board is made up of waterborne freight carriers and shippers with the express goal of providing advice to the USACE regarding infrastructure needs on the inland waterways.

In 2010, the Inland Waterway Users Board established a subcommittee to complete a comprehensive review of investment needs for the rehabilitation of the U.S. inland waterways system and to make recommendations for restructuring the current funding mechanisms. The Inland Marine Transportation Systems Capital Investment Strategy Team (IMTS-CSS) was composed of members from the Inland Waterways Users Board and USACE staff. In its report, titled "Inland Marine Transportation Systems Capital Projects Business Model," the IMTS-CSS recommended to Congress that it implement changes to the budgeting and selection processes for improving and expanding inland waterways infrastructure.

Due to rising costs for dam and lock projects, the report called for a large increase in infrastructure investment along with changes in the funding of projects. The report called for an increase of \$380 million per year for the next 20 years to fund new construction and rehabilitation projects.

Maintenance of the waterways is funded in part by the Inland Waterways Trust Fund (IWTF). The fund is designed to finance half the cost of new construction and major rehabilitation. The other half of the financing comes from the federal government through appropriations from its General Fund. The IWTF has several components, chief of which is a fuel tax paid by the carriers. In its report, the IMCT-CSS team recommended an increase of 30 to 45 percent in the current fuel tax of 20 cents per gallon, which translates to increases of 6 to 9 cents per gallon of fuel.

In regard to cost-sharing in the future, the report made the following recommendations:

- All lock construction projects should be cost shared, with 50 percent coming from General Federal appropriations and 50 percent coming from the IWTF. Lock rehabilitation projects that exceed \$100 million should be similarly cost shared.
- Construction and major rehabilitation of dam projects and lock rehabilitation projects costing less than \$100 million would be funded from general appropriations.

These two provisions would result in a funding system with the following breakdown: the IWTF would provide \$110 million each year and the federal government would appropriate \$270 million.

The Role of the States

Despite the federal government's exclusive responsibility for dredging channels and for upgrading and maintaining lock and dam infrastructure, the states that have commercially navigable rivers running through (or adjacent to) their borders also play an active role in shaping the operation of the inland waterways system. They have developed a variety of mechanisms to support and encourage waterway transportation and waterborne commerce. Openly viewing inland waterways as vital for maintaining the health of all industries that depend on the river for transportation, many states have created port authorities to invest in port infrastructure.

The financing of river ports varies from state-funded-and-owned ports to locally funded public port authorities that merely rent port facilities. Regardless of the financing mechanism, port facilitates establish intermodal terminals that serve as interfaces between waterborne commerce and landside transport. In this respect, they enhance the overall efficiency of the nation's transportation system, as rail and trucking facilities benefit from connection to port facilities.

States also support inland waterway transportation infrastructure upgrades by working with multistate stakeholder coalitions to influence federal funding for USACE lock and dam infrastructure improvements. Multistate stakeholder groups include the Ohio River Basin Alliance, the

Ohio River Valley Water Sanitation Commission (ORSANCO), and the Ohio River Basin Congressional Caucus.

Inland Waterways, Traffic Management and

Globalization has made traffic management on inland waterways around the world more politically and economically essential, and it has challenged local, state, and national authorities from Tampa Bay, Florida, to Singapore. Inland water transport creates environmentally friendly, cheap, and efficient transportation, but it also requires effective traffic management. The increase or decrease—depending on

location—in size and volume of vessel traffic combined with the physical characteristics of the waterway, rapidly changing weather patterns, political and economic fluctuations, development of infrastructure, and the entity managing the waterway requires traffic managers to continually organize and resolve vessel traffic situations.

According to Hans van der Werf, secretary general of the Central Commission for the Navigation of the Rhine, the challenges in inland water transport faced in Europe, North America, and Asia are all the same. He believes that some of the localized navigational problems like those involving vessel types and cargos can be solved with universal solutions.

Vessel Type and Traffic Fluctuations

Maritime traffic in both Europe and the United States must deal with vessel traffic fluctuations moving with political and economic conditions, making managing inland waterways difficult. In 2012, among the top five ports in Europe, Antwerp and Amsterdam in the Netherlands reported increases compared with the fourth quarter of 2011, while Hamburg, Germany, and Marseille, France, recorded decreases. Europe's inland waterway system is operating under difficult economic circumstances, with 80 percent of the fleet operated by owner-operators, making it difficult to match supply with demand and hampering the sector's ability to reinvest and innovate. Employment in the sector is estimated to have decreased 10 percent. The aging employee population, with 50 percent of the workers over 50 years old, is another management problem. The rapid growth of freight logistics markets and an already congested land-based infrastructure also makes innovation of vessels necessary.

Partial Air-Cushion Supported Catamaran

Partially developed with funding from the European Union, the Partial Air-Cushion Supported Catamaran (PACSCAT) is projected to be one of the vessel types of the future. The PACSCAT is a high-speed, low-wash, variable draught vessel designed to operate on the Rhine and Danube Rivers. Moving at a speed of around 23 mph (37 km/hr), the ship can make the more than 1,000-mile trip from Constanza, Romania, to Passau, Germany, in three days compared to the current voyage time of seven days by barge, which makes it compete on an equal basis

with road transportation. The PACSCAT's average speed of 22 to 24 knots can be increased to 40 knots in open water, such as on the Great Lakes under the right conditions.

The PACSCAT can carry 2,000 tons, which approximates about 45 truckloads, and its draught can be adjusted from 8 feet to as low as 5 feet to meet shallow conditions; air draught can be changed to allow for bridge height limitations. The air cushion is encased between the side hulls and end seals and installed lift fans generate it to reduce the propulsion power requirements—important features in waterway navigation. The PACSCAT is designed to use existing berthing or loading facilities. Designers say that PACSCAT features can be applicable to short sea operations, possibly with a river transit as part of the route to avoid unnecessary transshipment of cargo.

Container Ships

Incremental improvements in container ship design have transformed container ships from 10- to 15-knot vessels to 22- to 23-knot vessels, which compares favorably with the PACSCAT river vessels, which achieve 22 to 24 knots. Modern container ships can carry between 400 and 1,400 20-foot equivalent unit (TEU) containers, the standard freight carrying measurement for container ships. Container ships have a draft of approximately 2 feet, which can adapt to some navigational systems like the St. Lawrence Seaway, but the new Triple-E class container ships (the E representing economy of scale, energy efficiency, and environmentally improved) have presented costly and time-consuming problems for ports. Almost a quarter-mile long and taller than a 20-story building, the Triple Es can move goods more cheaply and efficiently than current ships, but they are too big for most of the world's ports.

Only a few European ports, including Southampton in the United Kingdom (UK), can handle the Triple-E container ships, and in 2013, no port in North America could handle them. They cannot fit into the Panama Canal locks and can just squeeze through the Suez Canal, so they will only travel the China-to-Europe route, bringing in goods and making the return voyage mostly empty except for cargos of scrap metal and plastic waste for recycling.

Shanghai is the leading container port in mainland China, with a 2005 total of 18.08 million TEU.

A barge on China's Grand Canal (the Hangzhou–Beijing waterway) in 2008. The Grand Canal is the longest human-made waterway in the world at 1,083 miles (1,743 kilometers). China's overall inland waterway network, also the largest in the world, has a navigable length of 76,736 miles (123,495 kilometers) and consists of over 5,000 rivers and tributaries.

The Shanghai Port Authority has converted general cargo terminals into container terminals and is constructing a new port at Yangshan Island south of Shanghai with 52 berths and a capacity of 20 million TEU, to be fully operational by 2020.

Tugboat Barges

Tug/barge vessels transport freight on many North American and European inland waterways, a practice that evolved on the Rhine–Danube River system to move containers and bulk cargo by making barge rates competitive with rail and truck. The German prohibition of trucks on German roads during weekends significantly improved barge competitiveness. Scheduled movements, current information systems, and the ability to provide a wide range of cargo-carrying options make tugboat barges a useful management option.

Tugboat barges are also important factors in Asian and African waterway maritime transportation systems. More than 80 percent of China's cargo

traffic travels on the Yangtze River and much of that on tugboat barges. Weak or nonexistent infrastructure, lack of current charts, and the Yangtze's bends and rapids are just a few Yangtze traffic management challenges.

The Amazon River system is the longest continuous navigable waterway in the world, with oceangoing vessels navigating as far 2,300 miles upriver, as far as Iquitos, Peru, with only shallow draft barges able to navigate the Amazon upstream south of Iquitos. Even though the Amazon is the primary river system in South America, it took until the 21st century for the Peruvian navy to complete a hydrological map of the Amazon and create electronic maps allowing draft tugs and barges to transport construction materials upriver to the natural gas fields on the eastern flanks of the Andes Mountains. A communications network for barges and tugs, a series of accurate charts, and modern ports are management tools important for future Amazon development.

Ferry Boats

The high-speed technology of the late 20th century and early 21st century increasing the speed of ferry services to 30 to 40 knots instead of the 15 to 20 knots of conventional ferries has revolutionized the nature of ferry operations around the world. The Stena Line, the biggest ferry operator in Europe, offers a large fleet and a wide selection of routes and destinations, including ferries in Ireland, Britain, and Holland. Stena Lines introduced the HSS 1500 between Dun Laoghaire in southern Ireland to Holyhead in Wales, a 70-mile route across the St. Georges Channel through some of the roughest waters around Britain. The new high-speed ferry reduced the voyage to two hours instead of the four-hour service in place when the route used conventional ferries. This speed change allowed Stena Lines to use one vessel instead of two for significant economic saving. The HSS 1500 can carry 350 TEU as well as 1,500 passengers.

The management issues with the HSS 1500 are concerns about its width, which at 131 feet would make it too wide for the Great Lakes St. Lawrence Seaway System locks, and its wake, which might be too powerful for river and canal operation. The European Union has been working to develop high-speed ferry technology for river work, especially for the Rhine and Danube Rivers.

U.S. Maritime Traffic Management

The U.S. inland and intracoastal waterway system is not as well-known as its airways and airports or railway or highway networks, but inland waterways are an essential and often overlooked part of America's freight transportation system, handling approximately 600 million tons and 300 billion ton-miles of domestic cargo shipments a year. Inland waterways are the primary artery for more than half of the nation's grain and oilseed exports, for about 20 percent of the coal for utility plants, and for about 22 percent of domestic petroleum. Most of the cargo is raw materials and liquid and bulk cargo like coal, petroleum, chemicals, grain, processed metals, food, farm products, and cement, sand, and gravel. The U.S. Army Corps of Engineers (USACE) has overseen and maintained the waterways since the 19th century, but in the 21st century, politics and special interest groups as well as economic pressures have affected the overseeing and modernization of the inland waterways.

Commercial towboats pushing barges lashed together as tows make up the majority of the inland waterway traffic. Each barge has a capacity of 1,400 to 1,800 tons of cargo and a single 15-barge tow carries the freight car equivalent of 870 tractor trailer trucks, creating an inexpensive and fuel-efficient method of freight hauling especially suited to bulk cargo that is not time sensitive.

In the United States, a system of 192 commercially active lock sites with 28 lock chambers provides navigation channels on nearly 12,000 miles of inland and intracoastal waterways. The USACE manages the system as part of its civil works program, and according to the USACE, the system is in peril. The infrastructure supporting this inland waterway system is aging, and a major failure of locks and dams could incapacitate the entire system. Age, time, and lack of maintenance are wearing down the reliability and capacity of the structure of inland waterways.

To complicate the situation, demand for freight transportation in America is escalating. The U.S. Department of Transportation's "Freight Analysis Framework" report forecasts a 70 percent increase in freight traffic by 2020. Traffic on inland waterways is forecast to increase by 51 million tons of freight from 2012 to 2020, and by 2040, the increase is expected to exceed 118 million tons. This growth will challenge the capabilities of the transportation systems, especially highways, but it will also impact rail and water transportation.

The marine ports system is especially important for America's international trade, valued at more than \$944 billion in imports arriving in the United States by water. America depends heavily on waterborne trade for its growing export markets, especially agricultural products, manufactured goods, and the exporting of energy and refined petroleum products. Even if growth slows worldwide and Europe continues to undergo economic problems, trade with Asia and Latin America and growth forecasts require major investments in U.S. marine ports.

Managing the St. Lawrence Seaway

According to a study of the St. Lawrence Seaway, a 2,300-mile inland waterway connecting the Great Lakes to the Atlantic Ocean, maritime traffic systems in the United States and especially along the St. Lawrence Seaway need a major overhaul to remain competitive in the global maritime system.

The study report, prepared for the U.S. Department of Transportation/Transport Canada and titled “Great Lakes-St. Lawrence Seaway New Cargos/New Vessels Market Assessment Report,” looked especially at cargos that have unique characteristics that make them susceptible to transportation management restrictions, including hazardous materials and cargo needing refrigeration, which subject them to increased handling costs and transportation restrictions. Maritime management might ban hazardous materials from critical bridges and tunnels, and cargo needing refrigeration has to be stored and moved in a timely manner.

System capacity is becoming an increasingly important factor in future shipping decisions, because planners anticipate that supply side limitations including labor—mostly the trucking industry—and infrastructure will make current distribution systems less cost effective and limit what they can carry. Cargo capacities of containers, vessels, and ports need to be carefully considered and factored into traffic management planning.

Managing the Upper Mississippi Inland Waterway

The U.S. Department of Transportation sponsored a 2005 study of traffic management on the Upper Mississippi River (UMR), which scrutinized traffic management on the river system. The study recommended that new traffic management policies including appointment and scheduling systems for vessel traffic not be implemented on the UMR because they would cost too much and create too many disruptions in the water transportation markets. The study stressed that evaluating new traffic management policies like appointment and scheduling systems should take place to determine the effectiveness of alternative management policies, as traffic levels have significantly increased and locks have degraded. The study recommended that vessel tracking systems for lockage or traffic management on the UMR should be designed to coincide with management alternatives, and that responsibility and legal authority for UMR lockage and traffic management should be clarified before implementing new and far-reaching lockage and traffic management systems. The study also said that traffic management policymakers should explore opportunities to partner with other agencies and private organizations to develop vessel tracking on the

UMR and strengthen the alliance with the Coast Guard in implementing vessel tracking systems.

Managing the Intracoastal Waterway

Extending for about 3,000 miles along the Atlantic Ocean and the Gulf of Mexico coasts in the southern and eastern United States, and spanning the five Gulf Coast states, the Intracoastal Waterway (ICW) is vital to the American economy, carrying one-third of the freight of all U.S. waterways. The USACE maintains the ICW, which is connected to sounds, bays, lagoons, rivers, and canals in many places and deep-draft vessels can navigate some portions of it. Protecting, maintaining, and improving the ICW ensures the future of many people and businesses depending on the efficiency and economy of barges and other vessels transporting cargo.

The USACE faces management challenges from environmentalists objecting to what they consider excessive dredging of some portions of the waterway and filling other portions of the waterway with what they consider unsafe materials.

Colorado River Locks

The Colorado River Locks provide a navigable waterway for towboat and other marine traffic while preventing the waters of the Colorado River from flowing into the Gulf Intracoastal Waterway where they intersect. The Galveston District USACE designed and built the Colorado River Locks in 1954 to allow vessels and barges to pass during high water in the Colorado River. During normal Colorado River conditions, they use the locks as floodgates to prevent silting in the ICW. The USACE maintains the locks and lock keepers are employed to assist vessels in their passage through the locks. Now nearly six decades old, the locks need constant maintenance and will eventually have to be replaced.

Institute of Traffic Engineers

In 1930, in response to the needs of the rapidly changing transportation sector, transportation officials interested in the emerging field of traffic engineering came together to establish the Institution

of Traffic Engineers (ITE). In 1975, the name of the organization was changed to the Institute of Transportation Engineers. ITE's membership of approximately 17,000 individuals and organizations in more than 90 countries includes not only traffic engineers but also a wide range of transportation professionals from the fields of transportation planning, consulting, education, and research. Belying its global membership roster, the major portion of the group's work is focused in the United States. In addition to the national headquarters, which is located in Washington, D.C., there are various regional and state ITE agencies that carry out the work of the organization.

As an organization that focuses on ground transportation, the mission of ITE is to assist transportation professionals in fulfilling the mobility and safety needs of states, regions, and nations. These goals are accomplished by applying technology and scientific principles to all fields of transportation. These fields encompass research, planning, functional design, implementation, operation, policy development, and management. ITE projects and activities include providing member support, encouraging education, stimulating research, developing public awareness, and promoting the exchange of information relevant to members of the transportation engineering sector.

A number of meetings and seminars are held throughout the year to facilitate the exchange of relevant information. These meetings deal with subjects such as planning, engineering and design, safety, mobility and operations, and implementing transportation solutions. By participating in professional development sessions during annual conferences, attendees earn credits in transportation engineering as approved by the International Association of Continuing Education and Training. Exhibits are always popular at ITE conferences, and they provide a channel for demonstrating new technologies and products. The *ITE Journal* is published monthly to further the goal of facilitating the exchange of information in the field. Throughout its history, the organization has also published a large number of handbooks and manuals for use by individuals within the field of transportation engineering. The success of the Internet has provided an additional avenue for exchanging information, and ITE's Web site enables access to an online bookstore that offers materials of interest to members of the transportation engineering community.

ITE recognizes excellence in the transportation engineering field by awarding the distinction of "ITE Fellow" to a limited number of individuals. The requirements for achieving this distinction are being a registered engineer, having demonstrated success at taking on responsibility for significant work in the field of transportation or traffic engineering, and contributing to the work of ITE or to the field of traffic engineering.

History

In the years following the end of World War I, the ever-increasing number of automobiles on American roads led to mounting traffic problems. In large cities, the addition of buses and streetcar tracks that frequently ran down the center of city streets made it even more difficult for automobiles to proceed safely and efficiently. The result was an increased number of traffic-related accidents in U.S. cities. These combined factors led to considerable pressure being placed on politicians to deal with problems that were beyond their individual abilities to handle. In turn, politicians turned to civil and electrical engineers for solutions in designing devices to regulate the flow of traffic.

Because no programs existed for training engineers to become experts in traffic engineering, they were forced to train themselves to deal with issues that arose in ground transportation, often learning by trial and error. While frustrating for engineers, this method of learning the field had the advantage of encouraging innovation. One such innovator was Charles Adler, Jr. (1899–1980). As an engineer who was also an inventor, Adler created the first traffic signal, a pedestrian push-button device that was installed at Falls Road and Belvedere Avenue in Baltimore, Maryland, in 1928. Some engineers chose to focus on designing roads with the goal of making them safer and more efficient. Because the field of traffic engineering was still so new, transportation engineers frequently sought advice from one another, and they tended to cluster together at the meetings of other professional groups.

Out of recognition of the need for both licensing and training, the idea of a professional organization for transportation engineers was born. On October 2, 1930, while attending the annual meeting of the National Safety Council in Pittsburgh, Pennsylvania, 30 transportation officials established the Institute of Traffic Engineers. The stated mission

of the new group was to provide a channel for the exchange of information, promote professionalism within the field, and encourage local and state governments to create transportation engineering departments to deal with safety and mobility issues on an ongoing basis. During the planning stages, there was considerable discussion about whether the group should be an organization for all individuals involved in the field or only for those with professional standing. The decision was ultimately made to establish the Institute of Traffic Engineers as a professional organization.

ITE's constitution and bylaws were approved at a subsequent meeting in New York City on January 20, 1931. The first president of the organization was Ernest P. Goodrich (1874–1955), a civil engineer who had been educated at the University of Michigan. After leaving office in 1932, Goodrich continued to be active in his field. He worked with the U.S. Navy and the New York City Departments of Public Works and Sanitation. He also worked abroad, participating in city planning in Nanking and Whampoa in China and in port facility planning in Bogotá, Colombia.

The role of ITE was strengthened during World War II, and the organization grew significantly in the postwar years. Creating regional and state divisions in the 1950s allowed the ITE to become more closely involved in promoting safety and mobility at lower levels and encouraged cohesion among experts in the field of traffic engineering. In 1975 the Institute of Traffic Engineers became the Institute of Transportation Engineers in order to more accurately reflect its membership.

Organization

Within the Institute of Transportation Engineers, approximately 11,000 members participate in the work of 12 special-interest councils. Each council publishes its own newsletter in order to keep members informed about new research, relevant issues, emerging trends, and proposed legislation. An international board of direction offers guidance to the various councils. Technical councils include Freight Mobility, Management and Operations/ITS, Parking, Traffic Engineering, Transit, Transportation Expert Witness, and Transportation Safety. Employer-based councils include Public Agency, Transportation Consultants, and Transportation Education.

ITE in Action

One of the ongoing responsibilities of ITE is to serve as the voice of the people by monitoring the efficiency of traffic-control devices. In 2005, for instance, ITE reported that many Americans were up in arms over the inefficiency of traffic lights that caused them to wait in traffic jams for extended periods, wasting gasoline and contributing to the air pollution caused by burning fossil fuels.

As reported by *USA Today*, ITE officials stated that of the 378 traffic agencies located in 49 U.S. states, two-thirds failed to engage in ongoing monitoring of traffic lights. ITE also contended that these traffic agencies failed to respond to problems as they arose. ITE expressed concern that a 2004 study conducted by Philip Tarnoff of the University of Maryland's Center for Advanced Transportation Technology had revealed that most states had not reset their traffic lights at all during the previous decade, despite major social and economic changes.

Integrated Transportation and Urban Land Use Planning Models

A transportation and land-use feedback cycle introduced by Michael Wegener and Franz Fuerst summarized that a transportation system creates spatial accessibility and that spatial accessibility influences location decisions for the land-use system. The land-use system—residential, industrial, or commercial—in turn affects the locations of human activities such as living, working, shopping, education, or leisure. These human activities form trip patterns in the transportation system. Because of this cyclic relationship between transportation and land use, several integrated models have been developed in the past few decades, including the original Lowry model, the Garin-Lowry model, the Integrated Transportation And Land-Use Model Package (ITLUP), the Projective Optimization Land Use Information System (POLIS), MEPLAN, Kim's Chicago model, and URBANSIM.

ITLUP is a Lowry-type model that combines two separate components: a land use model and a transportation network model. POLIS is a mathematical programming-based model formulated as a nonlinear mathematical programming in which locations of jobs and housing, and travel patterns are modeled simultaneously. MEPLAN is based on spatial input-output analysis developed by Marcial Echenique and Partners Ltd. in the United Kingdom. Kim's Chicago model employs an urban economics concept that integrates general system equilibrium with probabilistic spatial interactions, combines transportation-facility location models, and equilibrates demand and supply over networks. URBANSIM is a microsimulation model incorporating the interactions between land use, transportation, and public policy. This article focuses only on the two major and widely used integrated models namely Lowry (the original and Garin-Lowry) and URBANSIM models.

The purpose of land use-transportation models is multidimensional. The models estimate demands for employment, residential, commercial and other activities and integrate the demand with

transportation needs and supply. The models also help gain a better understanding of the urban areas for which transportation planning is necessary. Land use and transportation planning ideologies have changed from ideas of the 1950s and 1960s to the ideas of the 21st century. These planning ideologies were captured in different models that integrate transportation and land use.

Some of the past ideologies like the Lowry-type model called for planning to take into consideration the growth in urban areas and the values such growth would add to the labor force and retail sectors. In addition, since this model concentrated heavily on the growth of urban areas in terms of the increase in population and jobs, it did not take much into account the added need for multiple modes of transportation. However, a more current integration of transportation and land use planning models such as URBANSIM takes into account many more variables than the traditional ones, such as population, employment, and housing. With the URBANSIM model, users can account for other variables that are important in the 21st century, such as greenhouse gas emissions, environmentally sensitive habitats, and protection of open spaces.

Lowry-Type Model

The Lowry-type model was developed in 1964 by Ira Lowry for the metro area of Pittsburgh, Pennsylvania. The model represents well the relationships between transportation and land use. The model is a computer microsimulation model used to understand the spatial organization of human activities, taking into account public decisions (for example, urban renewal, tax policies, land use controls, and transportation investment). The core assumption of the Lowry model is that regional and urban growth (or decline) is a function of the expansion (or contraction) of the basic sector. This sector in turn has impacts on the employment of two other sectors, retail and residential. The model can account for variables such as employment and population by sectors in a region. The Lowry-type model focuses on the impact of urban growth and employment change on retail and residential areas. The model determines the retail and residential potentials based on labor force. The Lowry model considers three economic groupings: the basic sector, the retail sector, and household sector. The basic sector, or site-oriented as suggested by him, is where

all business, industrial, and administrative work taking place serves nonlocal residents. Next is the retail sector, which contains the same type businesses mentioned above but these businesses serve locals and the needs of the local employment force. Last of the three sectors is the household sector. This sector is one where there are high household populations, and the labor force in this area is correlated to the size of the population. In short, the model sums up the activities in a region into zones of 1 square mile, taking into account the amount of employment and site space occupied by each establishment. The model also accounts for the constraints created by buildings and zoning laws.

Studies have suggested that the Lowry model has some limitations; the major shortcoming of the model is that it is a static model, meaning it does not tell anything about the evolution of the transportation/land use system. Current economic changes are in the service (nonbasic) sectors, forming the foundation of urban productivity and dynamics in many metropolitan areas. Under such circumstances the model is likely to be inaccurate in the major service-oriented metropolitan areas of the 21st century. A way to overcome this issue is to consider some nonbasic service employment as basic. Also, the Lowry model does not consider movements of freight in urban areas, which are very significant and have impacts on the friction of distance.

The Garin–Lowry model incorporates interaction submodels that distribute all activities at every iteration of the calculation. A reformulation by Garin improved the original Lowry model in several ways. As summarized by Joseph Berechman and Kenneth Small, the entire Garin–Lowry model is in matrix notation, which simplifies the presentation of the model and exposes the underlying equilibrium inherent in the iterative solution procedure. The input data include zonal levels of basic employment, inter-zonal travel cost matrices for home-to-work and home-to-shopping trips, zonal levels of attractiveness for residential and service locations, and control parameters for the economic-based mechanism. Based on these inputs, the workers in the basic employment sector are allocated to residential zones. The incremental residential population and the resulting incremental dependent service employment are then calculated. This increment of employment is distributed to workplace

zones, and the corresponding increment in population is then derived and distributed spatially to residential zones. At each iteration, a check is made to ascertain that zonal densities of service and residential population are within preset bounds. If they are not, an iterative procedure is applied to reallocate the latest increments by changing the zonal attraction parameters. The Garin–Lowry model has been used successfully to replicate observed spatial distributions of land use activities and to analyze the impacts of major changes. The model has a simple structure and a spatial-allocation mechanism that mimics the randomness in the decisions of individuals.

URBANSIM Model

The origin of URBANSIM came from collaborate efforts by the Oregon Department of Transportation's Transportation and Land Use Model Integration Project (TLUMIP), the State of Utah's Quality Growth Enhancement Tool (UQGET), Envision Utah efforts, and the Oahu Metropolitan Planning Organization's investment in new land use and transportation planning models. According to the creator, Paul Waddell, in 1996 the TLUMIP initiated two models; first was the TRANUS model and second was the development of the URBANSIM model. Furthermore, TLUMIP use of the URBANSIM model extended to other planning regions of the United States, such as Honolulu, Hawai'i, and a prototype has been used in the Eugene–Springfield (Oregon) Metropolitan Area; testing data from 1980 to 1994 has given a verifiable justification of the model. Recent surveys show that URBANSIM has become the most widely used land use model system by planning agencies in the United States.

URBANSIM is a software-based simulation system for supporting planning and analysis of urban development, incorporating the interactions among land use, transportation, the economy, and the environment. URBANSIM is a collaboration by many planners and meant for the use of metropolitan planning organizations (MPOs), municipalities, cities, students, and researchers in order to investigate the effects on planning when multiple parameters, such as infrastructure, policy, accessibility, housing, habitats, and greenhouse gases, are taken into account. URBANSIM encompasses several theoretical models, such as random utility theory, urban economics/bid rent theory, hedonic price

theory, dynamic market equilibrium, microsimulation, and geographic information systems and spatial analysis.

More importantly, the URBANSIM model takes into account many factors in development, such as urban land, housing, nonresidential space, and transportation. By taking into account the developments and connections between government decisions and urban growth, URBANSIM maximizes its effectiveness in assessing the impacts and better influences planning decisions. Therefore, the model enhances the strategic planning capabilities of MPOs and other state and local agencies needing to evaluate growth management policies such as urban growth boundaries, assess consistency of land use and transportation plans, and address conformity with respect to air quality implementation plans. The URBANSIM model, as indicated in the work of Billy Charlton, is one that requires lots of input information, such as population and employment estimates, regional economic forecasts, transportation systems, and land use plans, land development policies such as density constraints, environmental constraints, and development impact fees. Once such information has been input into the URBANSIM system, it will come up with several alternatives and forecast scenarios. These scenarios can then be enhanced to meet the specific purpose of a project and compared to decide on a best alternative.

URBANSIM is great at separating its input component parts, such as households, business, and land use, and allocating importance to those that are chosen by the user and the available data. Once constructed to the specifications of the user, the output data can include future-year distributions of population, households by type (for example, income, age of household head, household size, presence of children, and housing type), businesses by type (for example, industry and number of employees), land use by type (user specified), units of housing by type, square footage of nonresidential space by type, densities of development by type of land use, prices of land, and improvements by land use. The output also includes transportation data such as accessibility, mode shares, vehicle miles traveled, congestion delay, etc.

that transportation planners face. These challenges now extend beyond unimodal planning to a more multimodal approach trying to improve interfaces across modes.

Background

The first ITS applications have their roots in engineers' early attempts to find more "intelligent" and effective ways to control road traffic. The first traffic signal control systems could be considered the first ITS systems. Since then, applications have been developed throughout the world, covering road traffic management and all other transportation modes' needs and making use of various technologies, as well as benefiting the transport industry and the public by providing effective and reliable traffic management and travel information provisioning schemes.

Besides infrastructure, ITS are now considered the most important factor that can effect cooperation among various transport modes to create a seamless transportation system across Europe. Important stakeholder communities (ERTICO, ITS-America, ITS-Japan, ITS-Germany, etc.) are providing or utilizing ITS applications and services and contributing to economic and social development.

Many countries have already created specific legislation related to the deployment of ITS. In the early 2000s, apart from national legislation, there was an effort to gradually put in place a legal framework at both a transnational (Europe, United States) and international level. Such efforts concluded with directives for the deployment of ITS, which sets the foundation for further legislative integration on behalf of the involved countries.

Technologies and Role

ITS applications make use of "telematics." The word *telematics* derives from the Greek words *tele* meaning "from a distance" and *matos* meaning "of its own accord." In recent years, telematics have been introduced to a significant portion of the transportation sector for both urban and intercity transport services. The use of telematics in ITS is provided through a variety of information and communication technologies. Regarding communications, ITS make use of Internet communications (online payment, routing based on real-time traffic information), mobile communications (travel information provision, routing based on real-time information) and various wave-transmitting communications

Intelligent Transportation Systems

Intelligent transportation systems (ITS) refer to all information and communication technologies (ICT) that are used in the transport sector, including in any kind of transport infrastructure and in any type of vehicle. The term *ITS* is defined as the applications of advanced technologies using computing systems, communications, appropriate infrastructure, and other electronic and non-electronic devices for the provision of more effective traffic and mobility management as well as a better level of transport services for travelers. ITS implementation is one of the cornerstones of modern transportation engineering as it provides great potential for tackling most of the challenges

(Bluetooth technology, microwaves). Geographical tracking position technologies are also included in the communications category, which includes automatic vehicle location systems (AVL) and the Global Positioning System (GPS). The information category includes traffic data collection technologies such as closed-circuit television (CCTV) cameras and sensor loops, as well as various software related to the statistical analysis of data, traffic assignment, routing algorithms, and more.

Traffic and Travel Information

Traffic and travel information (TTI) systems aim to provide information to travelers regarding their trip. Recent technologies make use of real-time data and provide online information regarding dynamic aspects of transportation (level of traffic congestion in urban areas, travel time, etc.).

TTIs are highly related to optimal use of traffic and travel data, including collection, processing, and final transmission. The main issues that transport planners have to deal with in the deployment of this type of ITS are the technical standards used and their interoperability, the legal framework and possible business models for TTI provision, and the extent to which travelers are reacting to the provided information.

Traffic and Public Transport Management

This category of ITS aims to improve traffic management in urban and interurban transport networks. It focuses not only on road transport but also on interfaces between road transport and other transport modes. Typical applications in this category are the intelligent traffic signal control systems, the incident detection and management systems, the systems providing priority to specific types of vehicles such as emergency response vehicles, the intelligent lane control systems, speed limit enforcement, longer distance diversions and rerouting, and floating car data collection systems.

All these applications have been used in previous decades for improving traffic conditions in traffic-burdened areas, at the same time increasing user safety and travel comfort. Research in this ITS field in regard to road traffic management has led to the development of traffic management tools and applications that many transport authorities in urban areas use in an integrated way through mobility management centers and traffic control centers.

Navigation Services

The introduction of satellite navigation technologies has enabled the development of navigation systems and services that include technologies related to identifying the position of a vehicle or load unit (positioning) and providing instructions for the optimal route to one's destination. GPS data is used for tracking vehicles and providing accurate positioning.

Vehicle tracking is mainly used in the freight transport industry to improve monitoring and securing cargo. Passenger transport ITS navigation systems couple navigation services with real-time traffic data in order to provide route guidance based on real-time traffic conditions.

ITS navigation services mainly use communication technologies and mobile cellular networks. The 3G communications protocol and the spread of wireless Internet technologies have contributed to the possibilities for exchanging larger amounts of traffic-related data, in real or near real time, at affordable costs.

Smart Ticketing and Pricing

ITS technologies provide services for the collection of fees (mainly tolls) both in intercity and urban pricing systems. In recent years, new technologies have enabled the upgrade of pricing policies, making it possible to introduce various fares in one specific system based on specific and socially fairer criteria (vehicle's emissions, level of noise produced, etc.). A specific area within this category is the "smart ticketing" systems, which refer to a more precise pricing of public transport based on the degree of usage of each mode and, at the same time, provision of various payment options and other services.

Through this type of ITS application, interoperability between various transport modes can be more effective in providing a fully multimodal transport network, especially in urban public transport systems. ITS applications that assist smart ticketing and pricing in the field of transport, especially in the road sector, will likely be commonplace in future urban and interurban networks.

Safety and Security

Safety and security are the most important factors in transport policies. A safety-oriented ITS system needs to provide real-time information

that will help drivers avoid a crash or mitigate the consequences of a crash. The ITS technologies in this category include “autonomous” solutions (for example, systems that concern only the infrastructure or are in-vehicle based), and “cooperative” solutions (employing vehicle-to-vehicle or infrastructure-to-vehicle communication of information and data). Furthermore, these applications could be categorized as “passive” or “active” safety systems according to whether they are (passively) preventing and protecting drivers and passengers in case of an accident, or (proactively) assisting the driver to achieve the desired level of safety.

Freight Transport and Logistics

ITS for freight transport and logistics are realized through a set of “intelligent” services such as application programs and technologies for gathering, storing, analyzing, and providing access to cargo data to help users make better decisions. ITS contribute to improving the efficiency of freight transport by developing interoperable information services at national and global levels and building on standardized data structures (for example, the DATEX II) and exchange services.

Intelligent Mobility and Co-Modality Services

Mobility management refers to the effective handling of the transport demand for a particular area. All previously mentioned categories can contribute to the promotion of intelligent mobility management as well as to the co-modality (cooperation between the modes).

Environmental and Energy Efficiency

The main objectives of ITS for energy efficiency are to help provide cleaner, more energy efficient, and safer transport. Most of the previously discussed categories can be included in this category as they can positively influence the environmental and energy efficiency of transport systems. However, there are some specific applications that are most directly relevant, such as environmental route guidance (to avoid forecasted congestion), ecodriving (environmentally sensitive driving), and more.

Intelligent Vehicle Highway Systems

The intelligent vehicle highway system (IVHS) represents a smart transportation system that utilizes technology to permit motor vehicles and roadways to communicate with each other via two-way communication devices. IVHS is anticipated to make travel by automobiles and other motor vehicles easier, faster, safer, more efficient, and more reliable by integrating features of travel by private vehicle with those of mass transit systems. In order to achieve this goal, IVHS works to integrate the flow of freight and passengers across transit modes in a manner that is convenient, efficient, and reliable. In designing programs to implement IVHS, special

care is taken to present solutions to bottlenecks that otherwise bedevil those using rail, roads, sky, sea, and waterways. With considerable support from the U.S. Department of Transportation (USDOT), IVHS will continue to evolve to provide safer and faster travel options for many.

Background

As technology has evolved, many policy makers and researchers have investigated smart transportation systems as a way to speed commutes, reduce fatalities, and reduce energy consumption. To that end, many corporations, universities, government agencies, and others have worked to make IVHS a reality. IVHS entails a series of automated highways that include a set of lanes that use specialized sensors and wireless communications systems that permit automobiles to travel under computer control at safely spaced intervals. To assist with this, IVHS explores how real-time traffic data can be collected and transmitted to the public in real time by means of dynamic message signs, instant messaging, and other means. This real-time traffic data can also be used to regulate ramp meters that improve the flow of traffic on highways and to synchronize traffic lights so that their times are adjusted in response to traffic patterns. To coordinate and fund these innovations, the USDOT created IVHS and has funded it through its Research and Innovative Technology Administration (RITA).

Development

RITA was founded in 2005 and serves as a unit of the USDOT. Initiated as part of the Norman Y. Mineta Research and Special Program Improvement Act, RITA is charged with advancing transportation analysis, science, and technology. RITA works to improve the coordination and dissemination of research related to these topics throughout the USDOT and throughout various corporations, agencies, and universities that are interested in developing new innovations related to transportation. With over 750 employees located throughout the United States, RITA concentrates on four areas of research development. First, RITA coordinates the USDOT's research and education programs, ensuring that interested parties are aware of innovative developments. Second, RITA shares advanced technologies that permit innovations within the transportation system. Third, industry

and researchers are provided with analytical, statistical, and other support to facilitate decision making related to transportation. Finally, RITA supports national efforts to disseminate information and provide training in transportation-related fields through funding and other encouragement. All of these efforts help support IVHS, which has been supported by the USDOT in earlier efforts since 1991.

RITA has funded IVHS as a means of improving what is known about how communications and information technology can enhance surface mobility and transportation safety. IVHS is also seen as an engine of economic development that can be used to support economic growth in the United States. The IVHS program has two areas of focus: the development of applications that focus upon the vehicle and the highway infrastructure, as well as applications that facilitate integration of the two. More recently, the focus of RITA has concentrated upon major initiatives, sometimes termed "targets for opportunity," that potentially have the chance to transform mobility, productivity, and safety. For this reason, investment in intelligent vehicles, intelligent infrastructure, and incorporating technological advances into the national transportation system have taken priority. Connected vehicle research has produced some of the most significant developments, as this technology can enhance safety, improve mobility, and benefit the environment. Connected vehicle technology (CVT) uses wireless communication devices to allow vehicles to communicate with other vehicles, the roadway infrastructure, and other sources of information. As these technologies have become more popular, they have become more common. Examples of CVT include geographic information systems (GIS), electronic toll collection, dynamic message signs, and coordinated traffic lights.

Global Positioning System Technology

Although IVHS is often portrayed in the media as a futuristic mode of travel, with smart cars seamlessly entering and exiting traffic with little or no supervision from their human occupants, real-life applications from research into this mode of transit exist today. Over the past decade, for example, Global Positioning System (GPS) data receivers have become a common feature in many motor vehicles. GPS uses a series of satellites that provide navigation

A variable speed limit sign on the Prague Beltway in the Czech Republic in 2010. Variable signs can be quickly modified to suit changing conditions, and dynamic message signs can display more extensive information and warnings about traffic incidents.

data to automobile and other transportation drivers. GPS technology permits information regarding the direction, location, and speed of a targeted vehicle to be shared with GPS transmitter units. This permits the data receiver to calculate directions, detect traffic interruptions, and increase the efficiency and safety of the transportation of people and goods. GPS has greatly assisted freight companies in plotting the navigation and timing of the shipment of goods, as it allows materials to be transported when the roads are least busy and when their conveyance is thus the most efficient and safe. As it has become more common, GPS data has come to be used by a variety of other users, including farmers, meteorologists, and others for a multiplicity of other uses.

Electronic Toll Collection

IVHS has also led to a variety of changes in how roadways are monitored and operated, including

electronic toll collection. Electronic toll collection uses “identification friend or foe” technology, originally developed for the military, to collect tolls electronically, thereby eliminating the delays caused on highways by toll collection. Owners of vehicles have the option to enroll in an electronic toll collection program; those who choose to do so receive a device that includes a transponder, which emits a signal that is detected when the vehicle is driven beneath sensors. A toll is then electronically collected through a debit system, which permits those enrolled in the program to proceed without stopping at a tollbooth. Those not enrolled in the program are directed to a tollbooth to pay in person, slowing their progress. (Those who evade payment by either method are subject to fines and other penalties.)

Many states, including California, Delaware, Florida, Illinois, Pennsylvania, and Texas, have adopted electronic toll collection systems, which have proven highly popular with commuters and other users. Road congestion is significantly reduced by electronic toll collection, as those enrolled in the program do not have to slow down to manually pay a toll. Some municipalities have explored using electronic toll collection as a means of reducing congestion further by charging variable tolls based upon demand, charging a higher toll at times of greatest use.

Signage

Dynamic message signs, sometimes referred to as “variable message signs,” are another innovation supported by IVHS. Dynamic message signs are electronic notices located along roadways that provide travelers with information about special events affecting travel. Warning travelers about accidents, congestion, road work, speed limits, or other incidents, dynamic message signs encourage or require travelers to take alternative routes, thereby improving safety and efficiency of travel. The dynamic message signs may be either permanent parts of the roadway infrastructure or temporary devices deployed for special circumstances. Messages include information about crashes, debris on the roadway, exit ramp closures, road closures, stalls, travel times, vehicle fires, or other data, such as Amber alerts related to missing children. By providing information regarding these events, dynamic message signs can mitigate the duration and impact

of such incidents, thereby improving the performance of the transportation system.

Vehicle Automation

A variety of vehicle automation innovations have also been developed as a result of IVHS. These innovations include autonomous cruise control, adaptive headlights, advanced automatic collision notification, automatic parking, and other devices. Autonomous cruise control automatically adjusts a vehicle's rate of speed so that a car or truck is able to maintain a safe distance from other vehicles. Adaptive headlights change the intensity or range of headlight beams in response to weather conditions, vehicle speed, and road situations.

Advanced automatic collision notification, commercially available from providers such as OnStar, assists emergency medical responders to make determinations regarding the severity of an accident and the treatment needs of the injured by sending crash data to monitors if a vehicle is involved in a severe collision. Automatic parking assists drivers seeking to park their vehicles, using sensors and other controls to steer a car into a parking space with little assistance from the driver. As innovations such as these become more common, IVHS will continue to evolve.

Interchanges, Modal

An interchange is a facility at a location where it is possible to transfer from one mode of transport to another. At one extreme, an international airport is an interchange, and at the other, the humble bus stop is an interchange between walking and bus transportation. Because no mode of transport can serve every geographic location economically, interchanges are locations where higher level modes (for example, a subway) can collect trips from lower level modes. This requires purpose-built facilities to make the physical transition from one mode of transport to another as safe and easy as possible. In this analysis, higher level modes are those with higher operating speeds and higher passenger capacity. The science of interchange design has advanced as a result of experience and market research feedback.

Location and Distribution

The location of interchange stations, especially park-and-ride stations, is very critical in terms of the site, ease of access, and passenger perception. A number of studies have been undertaken to examine the mathematical relationship between different modes of transport in a network hierarchy. Clearly, the larger the urban area, the more modes of transport that can be supported, and are needed, provided they are arranged to interchange smoothly with each other. This modal relationship is also affected by the relationship of the speed of operation of each mode, and hence the practical minimum distance between adjacent stops on a particular line.

If a city is divided for transit supply purposes into a number of geographic zones, like hexagons, then normally each zone will justify one interchange station. The only other factor will then be the number of lines that serves each interchange and the catchment area served by those lines. If buses are assumed to be the lowest mode in the hierarchy, do bus lines only serve a particular zone, or do they

cross zone boundaries? This is a problem for people living on zone boundaries. If bus lines only operate within a zone, then commuters may have to travel in the opposite direction to reach an interchange station, with a rail line linked to their ultimate destination. For many people this is counterintuitive. Cross-boundary bus services avoid this and also widen the market for transit.

The automobile made interchange station location in some ways easier and in other ways more difficult. If interchanges are located in the wrong place, commuters will drive all the way. So the location of interchanges must be based on a sound understanding of the travel market origin-destination pattern and commuters' perceptions of the ease or difficulty of interchanging. This is in addition to the fare structure and ticketing system, which impacts the utility of interchanges and the perception of the comparative cost of competing journey choices.

Number of Integrated Modes

Even in a city with competing modes of transport, like buses and taxis, it makes good sense for interchange stations to be provided, to enable modal cooperation, improve economic efficiency, and reduce environmental impacts. Sometimes interchanges may be provided by the operator of a higher order mode, (for example, rail) to encourage lower order modes to access and therefore "feed." This will stimulate modal transfer, especially from car trips. Interchanges can also be provided by major facility providers like shopping malls, sports arenas, etc., to improve access to the facility, widen the catchment area, and also as an investment in the urban infrastructure. Finally, interchanges can be provided by the municipality as a civic facility to allow different operators and modes to integrate the local transit network with nontransit modes like car and bicycle.

If the transit system is publicly provided, then the transit authority should be able to plan an optimized hierarchical network with a number of modes, both to expand the catchment area of transit and also to improve transit operational efficiency (supply side) and journey satisfaction (demand side). In a city of about 500,000 people, two transit modes can be integrated with interchange stations. In cities of over 1 million people, three transit modes are practical. The number of

modes, and therefore lines, will determine the number and location of interchanges.

Passenger Acceptance

Commuters do not like changing mode, especially for short journeys. There needs to be a combination of push and pull factors to make interchanging acceptable and attractive. A major push factor is usually widespread road congestion, making auto commuting slow and journey times unpredictable. A pull factor can be a parallel rail line, offering faster trips. In order to tie these together, considerable market research is needed to determine the best place for park-and-ride interchange stations.

From historical evidence of passenger and commuter behavior, interchange stations need to be located close to the origin of trips. A commuter who has to drive three-quarters of the way to the destination will not be tempted to switch to transit for the final quarter of the trip, even if parking at the destination is difficult.

Commuters are concerned with getting to work on time and more relaxed about the return journey home. So the link between the highway and the interchange station needs to be as short and easy as possible for the morning journey. Transit interchanges at highway interchanges are often an excellent solution.

Operating Problems

Most commuter trips are repetitive and planned before the start of the journey. So integrating highway congestion information with transit service information (for example, over the local radio/TV, Twitter or Internet, etc.) will greatly improve the probability of commuters switching and staying with transit via conveniently located interchange stations.

This, however, becomes problematic if the transit service is infrequent or unreliable. The transit operator can address the frequency question by better train and staff scheduling; a handy rule of thumb is that commuters will only use transit if the waiting time at the interchange is shorter than the ride time. There are various ways in which service frequency can be increased with a fixed number of trains (for example, improving operating speed, having a mixture of express and all station trains, etc.).

Improving service reliability is more challenging and requires a thorough understanding of the

causes of unreliability. These may be due to staff shortages, both drivers and maintenance staff, or equipment failures, or track problems. A comprehensive analysis of these causes should lead to a step-by-step program to improve reliability. Letting commuters know that trains are running reliably is another area, and good information at interchange stations is important but service information before leaving home vital.

Finally, the ideal interchange is one where there is a short walk on the level between each mode. Cross-platform bus and rail interchanges are practical, and car parking can be arranged to require the shortest practical walk. All this fails if there is no scheduling cooperation between operators. An incoming bus that just misses the train to downtown will not be an attractive service. Similarly, commuters returning home, seeing the connecting bus depart before the train arrives, will not continue interchanging for long. Operators therefore need to cooperate to ensure that services on different modes are scheduled to accommodate passengers who need to transfer and that they do so.

Multipurpose Sites

People do not naturally like changing modes, but if the utility of the interchange can be increased (for example, by making shopping possible), then there is a synergy to benefit the commuter, transit operator, and additional service provider. So, space at an interchange station can be franchised to a supermarket, a fast food outlet, bank cash machine, etc., allowing passengers to make use of the time interchanging to undertake another domestic requirement. This is especially true on the journey home, where a quick meal, urgent shopping, or getting cash can fill the space between getting off the train and getting back into the car to drive home.

Such multipurpose sites may result from serendipity of market forces or from careful planning and putting together a package attractive to additional service providers. Interchange stations will themselves have a large footfall that will provide a ready-made customer base for additional service providers. This justifies paying a site rent, which helps the transit operator offset some of the costs of building and maintaining the interchange.

Intermodal Freight Transport, Technology and

Intermodal freight transport involves the use of two or more carriage methods to move a shipment under a single freight bill from its point of origin to its final destination via road, rail, waterway, or air.

In the United States, intermodal freight transport is facilitated by both public- and private-sector enterprise. Federal, state, and local government entities typically are responsible for the underlying transportation infrastructure needed for intermodal freight transport, such as airports, roadways, and harbors. Private-sector industry generally manages the execution of intermodal freight transport, providing transportation equipment, carriage services, and logistical oversight. Both sectors work closely together to ensure the most efficient, cost-effective, and environmentally sound intermodal freight services to support international trade, U.S. industry, and the military supply chain.

Technological advances in intermodal freight transport over the years have made it easier to manage and track the transfer of goods between transportation modes and to coordinate the actions of

the various players involved in moving a shipment through the delivery chain to the end customer. The results have been greater flexibility for shippers and additional opportunities for cost savings.

Innovations in Intermodal Transport

Integrated intermodal transport is critical to the successful execution of national and international supply chains. Most bulk commodities, including food products, natural resources, and large building materials utilize multiple channels of transport to bridge the distance between site of origination and ultimate location of use. Consider grain, for example. In the United States, grain is typically transported from the originating farm via truck before being transferred to containers that travel by rail, water, and/or air before reaching their final destination at home or abroad. Even semibulk or small packages utilize intermodal transport, often moving from truck to rail or air for shipment to ensure the timeliest delivery to final destination in today's increasingly demanding and globalized markets in which sourcing options and trading patterns continue to expand.

In the modern intermodal environment, customers expect highly coordinated and customized delivery of goods via the supply chain. That means that intermodal infrastructure, equipment, technology, and operations must continually innovate to achieve maximum speed, reliability, flexibility, cost-effectiveness, quality, and consistency throughout every stage of the intermodal freight transportation process. Many of the innovations occurring in the intermodal arena have centered on technology.

Technologies such as smart cards, laser scanners, and Global Positioning System (GPS) data inventory tracking have significantly enhanced intermodal freight operations by streamlining processes and increasing visibility along the delivery chain. In the trucking industry, radiolocation technologies have bolstered the logistical management side of intermodal operations by combining automated vehicle location capabilities with voice and data communication channels to facilitate fleet dispatch and timely solutions to unexpected issues along the transport route. Rail transport has been bolstered by real-time grade-crossing, warning system, and interlocking control technologies. Additional innovations in intermodal rail have included the development of an intelligent railroad system with train

control and dispatching functionality to facilitate rail operations and maintenance, a national system to improve tracking and efficiency, and automatic equipment identification tags. Intermodal aviation has been aided by advances in the air traffic control system, including state-of-the-art weather and communication systems, enhanced navigation aids, and direct data links.

Across all modes, further efficiencies are available through application of electronic data interchange technologies that enable easy access to collective information and streamlined controls and processes intended to ensure that transportation efficiencies are maximized.

In addition to transportation system technologies, innovations in the design of intermodal transportation equipment have led to important efficiency improvements. In containerization, for example, design innovations have increased standardization and modularization of freight containers, making it easier, safer, and more economical to move, stack, and ship containers via multiple modes. Special "tanktainers" in which a tank is fitted inside a standard container frame to enable transport of liquids, and lightweight swap-body containers that feature folding legs under the frame to permit easy transfer without a crane are other design advances in containerization that have increased productivity within the intermodal process. The use of advanced materials also has made it possible to increase container capacity and life cycle, reduce overall container weight, and enhance container performance through climate control and other use-related technologies.

In intermodal rail, design enhancements have resulted in flat car improvements such as lightweight articulated rail cars. The modern cars are less costly to purchase, less expensive to maintain, and help protect cargo by eliminating potentially damaging slack action and roll dynamics between railcars. In terms of motor carriers, design advances have provided stronger but lighter trailers that generate fuel efficiency benefits and expand cargo capacities. Design enhancements were also behind the creation of FastShip technology, which couples a patented hull and propulsion system for cargo shipping vessels with dedicated loading systems that enable rapid transit and consistent freight handling almost anywhere around the globe.

A crane lifts a Toll Holdings container off a train in an intermodal container facility in Melbourne, Australia, August 2013. Improvements in freight transport technology have included design enhancements for intermodal railcars such as these. The new cars have lower maintenance costs and are designed to better protect cargo in transit. Other rail transport improvements include the use of the Global Positioning System and automatic equipment identification tags to improve tracking.

Federal Involvement

The Transportation Equity Act for the 21st Century (TEA-21), enacted in 1998 as a successor to the Intermodal Surface Transportation Efficiency Act of 1991, established a strategic planning process to set, monitor, measure, and report on technology research and development priorities related to surface transportation across the United States. In conjunction with TEA-21, the Office of Freight Management and Operations was created in 1999 under the U.S. Department of Transportation's Federal Highway Administration Office of Operations.

The Office of Freight Management and Operations supports the efficient, seamless, and secure flow of freight via the U.S. transportation system and across international borders to help sustain the economy and encourage global connectivity and commerce. Toward that end, the Office of Freight Management and Operations conducts

research, develops analytical tools and data, and assists transportation and planning professionals in obtaining required knowledge and skills to perform their jobs effectively. The organization also reviews state applications for funding, provides funding for significant projects, conducts operational tests of technologies, promotes standards for freight information exchange, certifies state compliance with federal truck size and weight standards, and provides information on state enforcement activities, reporting requirements, and contacts. Taken together, the activities are intended to foster a greater understanding of freight transportation issues and trends, cultivate public/private partnerships, improve operations through advanced technologies, and support the education and training of freight transportation professionals.

The Intermodal Freight Technology Working Group (IFTWG) operates in conjunction with the

Office of Freight Management and Operations. The IFTWG serves as a public–private partnership that pulls from the shared experience and funding of its diverse members to identify, assess, and recommend technology-based solutions to advance safe and efficient intermodal freight movement. The Intermodal Freight Technology program under the Office of Freight Management and Operations is charged with conducting operational tests of recommended intelligent transportation systems (ITS) technologies and developing standards for exchange of electronic freight data.

The ITS is designed to aid cooperation, integration, and technology application for improved productivity among regional transport operations through advanced communication technologies. Intelligent transportation systems range from installed electronics components to wireless technologies that can be integrated into the transportation infrastructure and equipment—including vehicles themselves—to help relieve traffic congestion, enhance transit safety, and optimize the administrative and operational efficiency of commercial and consumer transportation activities. Increased efficiencies consequently reduce operating costs, improve transportation system capacity, and lessen environmental impact.

Benefits

Successful deployment of intelligent technologies in intermodal freight transportation not only provides benefits for the freight network but also delivers significant advantages to both the private and public sectors. In the private sector, the key benefits from intelligent transportation technologies are tied to increased efficiency, enhanced service and reliability, and improved shipment integrity.

In the areas of efficiency and productivity, advances have been driven by better utilization of personnel and equipment. Automated tools that facilitate intelligent freight data have enabled freight operators to reduce administrative burdens, condense processing times, and shorten cycle times. Automated interfaces with regulatory agencies similarly have helped reduce border-crossing delays, nonproductive waiting time, emissions, and wasted fuel due to idling. Improved visibility combined with upgraded control systems have diminished the occurrence of errors overall and increased the speed and ease with which errors are remedied

when they do occur. All these components make it possible to significantly reduce the overall cost of doing business in the intermodal freight arena.

Better visibility and control through the use of intelligent freight technology also has increased operational flexibility and reliability, leading to improved service levels. Intelligent technologies permit operators to maintain schedule adherence by allowing them to identify and address disruptions and delays earlier and avoid shutting down the just-in-time production line. Similarly, carriers have the ability to respond more rapidly to changing priorities tied to in-transit shipments, such as route diversions, and to devise solutions to unexpected problems. The resulting improved reliability and quality of service increase both shipper confidence and overall customer loyalty.

Transportation technology advances have supported improvements in shipment and service integrity as well. Specifically, identification and validation tools such as biometrics and smartcards have increased security by reducing the risks associated with unauthorized pickup and delivery of intermodal freight shipments. Asset tracking technology and onboard sensors also have bolstered shipment security in the post–September 11 environment where the focus of protection has expanded beyond theft and contraband like narcotics to include safeguards against terrorism.

Intelligent freight technologies generate advantages for public enterprises and consumers as well. As in the private sector, public agencies and individuals glean benefits as a result of efficiency, productivity, and service quality improvements deriving from the use of advanced transportation technologies. One of the most significant rewards for the public at large is increased safety as a result of new technology applications. On a national scale, intelligent freight technologies augment security against terrorism and thus contribute to improved overall national safety. On a significant but smaller level, intelligent freight technology deployments can yield important safeguards during the transit process. For example, onboard vehicle sensors may decrease the number of crashes by calling driver attention to faulty equipment such as underinflated tires prior to actual equipment failure. Tools used to monitor driver performance similarly can reduce fleet incidents by identifying potentially unsafe driver behaviors in advance, thereby enabling providers

to educate their personnel on appropriate activity. Motion sensors at weigh-in stations can help improve enforcement and reduce the number of incidents related to overweight conditions of transportation vehicles. The greater visibility provided by intelligent freight technologies makes it possible for public agencies to reward quality shippers and carriers while focusing their enforcement attention on poor performers to yield the greatest benefits.

Superior emergency response is closely tied to safety, and intelligent freight technologies contribute directly to enhancements in that area. Advanced technologies surrounding emergency response warnings have increased the speed of notification regarding hazardous materials incidents, leading to increased effectiveness of incident response and reduced consequences in terms of both environmental mitigation costs and public exposure.

Intelligent freight technologies have led to other environmental and quality-of-life benefits such as reduced traffic congestion and emissions, increased mobility, and improved capacity of the transportation infrastructure. For example, the diminished congestion resulting from easing traffic flows around major transportation hubs like water ports, border crossings, and intermodal terminals means that fewer vehicles are stuck in traffic expending fuel and polluting air quality. Reduced traffic congestion also causes less stress on affected neighborhoods and trims the amount of time wasted sitting in traffic.

Intelligent transportation technologies have improved the quality, efficiency, and economics of intermodal freight networks, enabling better planning, execution, and cost benefits of goods movement via multiple transportation modes globally. The freight network improvements have spurred overall demand and supply for goods and services through the enhanced supply chain, which has stimulated international economic growth and sparked changes in how industry as a whole prices, produces, and delivers its commodities.

Intermodal Surface Transportation Efficiency Act

The Intermodal Surface Transportation Efficiency Act of 1991 (ISTEA, pronounced ice tea), was the first major federal transportation legislation to shift priority from building interstate highways toward ensuring and maintaining a fully integrated transportation system linking roads, rail, air, and marine transportation to support the nation's increasingly complex needs. This legislation significantly changed the intergovernmental transportation project planning process, restructured the states' reimbursement rates to make nonhighway and maintenance projects more attractive, defined a National Highway System linking major population centers, and strengthened the role of metropolitan planning organizations (MPOs). While the added flexibility for states to divert federal funds to projects such as mass transit did not have as much effect as expected, ISTEA marks a transition away from federal legislation dominated by the highway lobby and opened an opportunity for states to change their patterns of surface transportation spending.

The Legislative and Political Process

By 1991, the interstate highway system was largely complete, but reports showed that many of the nation's roads and bridges needed extensive repairs. With increasing global competition, many cost-conscious U.S. corporations were shifting to just-in-time delivery systems from suppliers and to markets; this added pressure to view a well-functioning multimodal transportation system as a national economic priority. Despite relatively wide consensus on the need for federal action, proposed solutions and ways of paying for them were much more contentious. The final version of ISTEA was the product of significant political compromise, taking elements from Senate and House of Representatives bills that differed both from each other and from the administration's proposed plan.

The Surface Transportation and Uniform Relocation Assistance Act of 1987 (STURAA) was due to expire in February 1991. President George H. W. Bush's proposal to renew it generally maintained the status quo with marginal increases to overall spending, to \$105 billion over five years. His plan proposed designation of a system of highways of national significance and offered lower reimbursement rates to states for projects not considered to have national significance, such as mass transit programs and most noninterstate highways. However, state and local officials would have more power in the project selection process through a highways block grant aimed for those roads not in the primary system.

The Senate bill's primary author was Senator Daniel Patrick Moynihan of New York, chair of the Senate Subcommittee on Water Resources, Transportation, and Infrastructure. Moynihan believed that transportation reform was needed and that continuing to heavily fund new highway construction to deal with congestion was a failing strategy. Moynihan and his allies argued that the funding structures used in prior legislation had encouraged building new highways even when concentrating on maintenance of existing roads or developing other means of transportation would provide more cost-effective or environmentally sound solutions. Whereas the president's proposal offered state and local officials increased project flexibility but provided incentives to direct funding toward a subset of highways, the Senate bill sought to level the playing field among different kinds of transportation projects.

The Senate bill thus reflected the most striking departures from previous policies. In deference to the president, the Senate bill proposed a National Highway System and a Surface Transportation Block Grant. However, the \$123 billion total proposed spending (over five years) was \$18 billion more than the president's plan. It featured a large increase for mass transit funding to \$21 billion (\$5 billion more than requested in the administration plan) and continued operating assistance to existing transit systems. While the Bush plan reimbursed mass transit projects at 50 percent for new starts and 60 percent for capital projects, urban and rural highways at 60 percent, 75 percent for noninterstate National Highway System roads, and 90 percent for interstates, the Senate plan set rates at 80 percent for all types of maintenance projects and 75 percent for new construction. In addition, presumably to combat antiurban bias, Moynihan added more authority for MPOs to be involved in transportation decision making.

Meanwhile, the House Transportation and Infrastructure Committee designed a bill more aligned with the highway lobby's interests. It featured the largest total authorization, \$151 billion (over six years), and kept separate programs and funding levels for urban highways, rural highways, statewide highways, and bridges instead of including the block grant as proposed by the president and Senate. The six-year timeframe was intended to put federal transportation funding on a more predictable long-term basis in line with planning and programming schedules. It also extended half of the five-cent gasoline tax that was set to expire after fiscal year 1995 and introduced measures to ensure states that 90 percent of the federal fuel tax collected in a state would return to that state. The House bill did reflect Senator Moynihan's argument for leveling the playing field by setting reimbursement rates for most programs at 80 percent and at 90 percent to 95 percent for interstate construction and maintenance projects.

The final bill (resulting from Senate and House reconciliation) included the House's six-year scope and \$151 billion price tag but kept many of the innovations proposed by the president and Senate. The final bill's statement of policy declared its mission to "develop a National Intermodal Transportation System that is economically efficient and environmentally sound." While ISTEA's funding

categories matched those of the Senate bill, the funding levels were generally closer to the House's levels. ISTEA also extended the fuel tax and its dedication to the Highway Trust Fund (HTF). ISTEA kept the House's 90 percent Minimum Allocation and Donor State Bonus, intended to address concerns by the states over equity between contributions to and allocations from the HTF. It assured that states would receive at least 90 percent of their respective contributions to the HTF for all highway programs with the exception of special projects. It also ensured that state shares from the HTF would not be reduced from previous years. Funds were also set aside to reimburse states for their costs of constructing highways that were later incorporated into the interstate system.

The creation of a National Highway System and the \$24 billion block grant system were both retained from the Senate bill. Up to half of any state's national highway funds could be shifted to other highway or mass transit projects as long as states could demonstrate upkeep of the designated roads, and those states and metro areas with acute air pollution problems (nonattainment areas) could transfer all funds to mass transit with permission from the U.S. Department of Transportation. Within the \$24 billion Surface Transportation Block Grant, 10 percent of funds were set aside for transportation safety programs and another 10 percent for transportation enhancement activities such as landscaping, converting unused rail corridors to bicycle trails, or removing roadside advertising. States could use remaining funds on a variety of other projects, such as covering planning costs or parking projects. In areas with populations exceeding 200,000, \$9 billion from these funds were required to pass directly to MPOs, allowing them power to make some project selection decisions without state approval for the first time.

ISTEA significantly strengthened the metropolitan planning process and expanded the role of MPOs in this process by requiring their involvement in project selection and transportation decision making. The legislation continued previous planning requirements for MPO involvement in urbanized areas with populations 50,000 and over. Large urbanized areas with populations over 200,000 were designated as transportation management areas (TMAs), and additional planning requirements applied to these TMAs. Each metropolitan area

had to prepare and update a long-range transportation plan and public comment was required before the plan could be approved. ISTEA required MPOs to consider 15 factors in their planning; including, for example, preservation of existing transportation facilities, reviewing and preventing congestion, connectivity of roads within and outside the metropolitan area, efficient movement of freight, and use of life-cycle costing in the design and engineering of bridges, tunnels, and pavement.

Other changes included instituting new planning requirements and management systems for things like traffic congestion and pavement maintenance. ISTEA also added mandatory seat belt and motorcycle helmet safety laws. Failure to adopt these laws by fiscal year 1994 meant automatic allocation of up to 3 percent of a state's highway funds to safety programs. ISTEA also softened the federal stance on tolls, allowing tolls on federal-aid highway facilities to a much greater extent than previous legislation. Initial construction of toll facilities, 4R (restoration, resurfacing, rehabilitation, and reconstruction) work on toll facilities, and conversion of free highways (except interstate highways), bridges, and tunnels to toll facilities became eligible for federal funding.

Implementation and Gradual Change

ISTEA is considered by many to be landmark legislation that has shaped the post-interstate transportation landscape, yet the change it effected was slow to occur. Although ISTEA added considerable amounts of flexibility for states' use of federal funds, most spending patterns did not shift very quickly. With flexibility came a more complex, decentralized planning process, with long-term and short-term statewide transportation plans required for the first time. The U.S. Department of Transportation took nearly two years to issue planning regulations; many states, fearing sanctions, awaited these regulations before implementing major planning process changes. Additionally, most highway and mass transit projects require several years to come through the pipeline from conception to planning and budgeting to construction and use; even if shifting federal funding to other projects had been desirable given the new reimbursement levels and ability to do so, large amounts of funding already were committed to ongoing highway projects. Further complicating matters, most MPOs did not have

staff or procedures needed to assume the full scope of responsibility assigned them via ISTEA.

Another reason for only gradual change under ISTEA was that while the legislation entrusted more power to MPOs, the balance still favored state transportation agencies. Despite mutual veto powers, if the state department of transportation vetoed an MPO's improvement plans, the metropolitan area could lose its ISTEA funds. If the MPO vetoed a department of transportation plan in its jurisdiction, on the other hand, the project might not go through, but the state could apply the funds elsewhere. Hence, even MPOs with the capacity to win consensus on transit projects often hesitated to enter conflicts with the frequently prohighway cultures in the state departments of transportation.

While implementation issues certainly contributed to the slow pace of change, perhaps the largest impediment was the fact that the public simply did not demand change. The great majority of trips in the United States are by automobile. This public preference is also reflected in state laws requiring that state fuel taxes be used for highway construction or maintenance projects. Since most transportation projects are funded by combination of federal and state funds, this creates a further bias toward using federal funds for roads.

ISTEA called for designating a National Highway System so that states would focus federal funds on infrastructure critical to maintaining a nationwide transportation network, but the law did not specify which roads would supplement the Interstate Highway System to form it. State, local, federal, and Department of Defense officials had two years to identify a system of high-priority routes considered essential for interstate and international commerce, defense, and access to intermodal transfer points, which was subsequently authorized through the National Highway System Designation Act of 1995. The resulting 160,000-mile system was only 4 percent of the nation's public roads, but it carried more than 40 percent of its highway traffic, 75 percent of freight traffic, and 90 percent of tourist traffic.

ISTEA required states to develop and implement management systems for pavement, bridges, safety, congestion, public transportation, and intermodal systems. These systems were meant to encourage efficient and effective maintenance decisions. For each system, states were to identify performance measures, collect data, and determine appropriate

strategies to address any problems. Interim rules issued in December 1993 set a timeline for full systems compliance by October 1996—just before ISTEA was set to expire.

Legacy

ISTEA's legacy is a mixed one. On one hand, ISTEA marked a sharp departure from a U.S. consensus that building highways was the sole priority of federal transportation legislation. Those hailing it as revolutionary have a legitimate basis for doing so; it rewrote the planning process and changed state-local relationships within it, leveled funding so that pursuing projects other than highways became more attractive, and established an intermodal, systemic paradigm for prioritizing spending. As a direct consequence of the more distributed planning process, planning and administrative costs more than tripled in the next 10 years, from \$267 million to \$893 million, and subsequent transportation bills struggled to find a balance between streamlining the process for practicality and adding even more required considerations and stakeholder participation.

On the other hand, substantive changes based on this broader focus were slow to develop. While the amounts of money flexed toward nonhighway projects increased every year under ISTEA, by the end of 1996, states transferred only 4 percent of the funds that they could, and almost all of that occurred in just three states. The extended difficulties passing TEA-21 and SAFETEA-LU, the next two reauthorizations for overall federal transportation funding, confirmed transportation policy's move toward conflict politics, but these bills also continued ISTEA's direction toward incorporating intermodal and environmental concerns.

International Air Passenger Transport

Air transport is a major driver of social and economic change. Despite recent economic shocks and a general downturn, air transport remains resilient, with the major aircraft manufacturers—Boeing and Airbus—forecasting that world passenger traffic will continue to grow 5 percent annually over the next 20 years. International air transport is increasingly important for a number of economic reasons. For example, it enables the movement of perishable and high-value goods over long distances efficiently and facilitates face-to-face business interaction. The following, however, focuses on the passenger side of the international air transport industry. It will look at the social and individual effects and attributes of this mode and examine the ways in which air travel benefits people worldwide.

Air travel demand has grown by around 5 percent annually for the past 20 years according to the International Air Transport Association (IATA). Even in 2012, when economic activity and prospects globally had not been particularly optimistic, there was a 5.3 percent increase in passenger demand. Now, over 51 percent of international tourists travel by air, according to the Air Transport Action Group (ATAG). Recent forecasts by the U.S. Federal Aviation Administration (FAA) suggest that airline passenger travel will almost double in the next 20 years. In 2011, over 2.8 billion people were carried by airlines around the world. In addition, ATAG reports that, worldwide, more than 56 million people work in aviation and related tourism jobs. This shows that international passenger air transport continues to be central to an ever more connected world.

Traditionally, air passenger transport has been seen as a major driver of tourism, with the establishment of routes between source locations and tourist destinations seen as key to encouraging inward investment in the local industry and allied tourism infrastructure. Thus, international air passenger transport was an important development tool in areas such as the Caribbean and the southern European destinations of Spain and Portugal.

In less developed countries, air transport provides a vital component of the tourism package and is seen as a main device to drive economic growth and consequent poverty reduction. The United Kingdom think tank, the Overseas Development Institute, suggests that three-quarters of tourist journeys start in a high- or upper-middle-income country and 40 percent of these end in a developing country. This highlights the importance of international tourism, and thus air passenger transport, to the transfer of financial resources to countries where they can help alleviate economic challenges.

In terms of governance, the International Civil Aviation Organization (ICAO) is a specialized United Nations agency that works toward the safe and orderly functioning of worldwide civil aviation. To this end, under the framework of the 1944 Chicago Convention on International Air Transportation, it provides the standards and sets out the regulations for aviation safety, security, efficiency, and regularity, as well as environmental protection with respect to aviation.

The ICAO was also responsible for developing the system of air traffic rights, known as freedoms of the air. While national governments are responsible for their own aviation policies, they work with other countries to negotiate bilateral agreements to allow international air transport between the two nations. This can result in a complex web of more than 10,000 bilateral air services agreements (ASAs) between each pair of countries. In air services negotiations between countries, the freedoms of the air provide the framework of rights around which agreements are made. ICAO's *Manual on the Regulation of International Air Transport* sets out these freedoms as follows:

First Freedom of the Air. The right or privilege, in respect of scheduled international air services, granted by one State to another State or States to fly

across its territory without landing (also known as a First Freedom Right).

Second Freedom of the Air. The right or privilege, in respect of scheduled international air services, granted by one State to another State or States to land in its territory for nontraffic purposes (also known as a Second Freedom Right).

Third Freedom of the Air. The right or privilege, in respect of scheduled international air services, granted by one State to another State to put down, in the territory of the first State, traffic coming from the home State of the carrier (also known as a Third Freedom Right).

Fourth Freedom of the Air. The right or privilege, in respect of scheduled international air services, granted by one State to another State to take on, in the territory of the first State, traffic destined for the home State of the carrier (also known as a Fourth Freedom Right).

Fifth Freedom of the Air. The right or privilege, in respect of scheduled international air services, granted by one State to another State to put down and to take on, in the territory of the first State, traffic coming from or destined to a third State (also known as a Fifth Freedom Right). ICAO characterizes all “freedoms” beyond the Fifth as “so-called” because only the first five “freedoms” have been officially recognized as such by international treaty.

Sixth Freedom of the Air. The right or privilege, in respect of scheduled international air services, of transporting, via the home State of the carrier, traffic moving between two other States (also known as a Sixth Freedom Right). The so-called Sixth Freedom of the Air, unlike the first five freedoms, is not incorporated as such into any widely recognized air service agreements such as the “Five Freedoms Agreement”.

Seventh Freedom of the Air. The right or privilege, in respect of scheduled international air services, granted by one State to another State, of transporting traffic between the territory of the granting State and any third State with no requirement to include on such operation any point in the territory of the

recipient State, i.e the service need not connect to or be an extension of any service to/from the home State of the carrier.

Eighth Freedom of the Air. The right or privilege, in respect of scheduled international air services, of transporting cabotage traffic between two points in the territory of the granting State on a service which originates or terminates in the home country of the foreign carrier or (in connection with the so-called Seventh Freedom of the Air) outside the territory of the granting State (also known as a Eighth Freedom Right or “consecutive cabotage”).

Ninth Freedom of the Air. The right or privilege of transporting cabotage traffic of the granting State on a service performed entirely within the territory of the granting State (also known as a Ninth Freedom Right or “stand alone” cabotage).

The term *cabotage* is defined in more detail under the 1944 Chicago Convention as the following:

Each contracting State shall have the right to refuse permission to the aircraft of other contracting States to take on in its territory passengers, mail and cargo carried for remuneration or hire and destined for another point within its territory. Each contracting State undertakes not to enter into any arrangements which specifically grant any such privilege on an exclusive basis to any other State or an airline of any other State, and not to obtain any such exclusive privilege from any other State.

This background of complex intercountry negotiation over air links highlights the dominance of this mode as a facilitator of travel across national boundaries. Air transport enables larger distances to be traveled with greater speed than any other mode, and for business travel, it provides connections across a global marketplace. For leisure travelers, air transport facilitates trip-making that satisfies a number of needs. It can form an important part of a wider tourism package, enabling visits to recreational destinations such as the cities of Europe (the region with the highest inbound international traffic flows). It can also be an enabler of travel that strengthens and binds people’s social links, as it allows those who are located in home countries to

A moving walkway at Chicago's O'Hare International Airport. O'Hare is among the busiest airports in the world, consistently ranking among the top 10 in the world in terms of number of passengers. The airport served nearly 66.8 million passengers out of the total 2.8 billion people carried by airlines worldwide in 2011. Over 51 percent of international tourists travel by air, and airline passenger travel around the world is expected to almost double in the next two decades.

visit those who now live overseas and vice versa. The importance of such travel can be seen on a daily basis at airports such as Miami International, where passenger flows between Latin America and the Caribbean and South Florida form a key component of traffic volumes.

Turning now to some of the important themes in passenger air transport, the most dominant change in the industry over the past 15 years has been the rise of the low-cost carrier. It began with Southwest Airlines in the 1970s, and by the 2000s several airlines with a similar model of service were in operation. Their success is based on high aircraft and seat utilization rates, low fares, no-frills, point-to-point service (often into secondary airports where charges may be lower), and quick aircraft turn-arounds. These airlines tend to operate on shorter haul routes, facilitating travel in dense markets such as Asia and Europe. Along with Southwest, Ryanair

and AirAsia are some of the other dominant carriers in this industry sector. In terms of the direct social impact of such operators, they have been seen to offer more people the opportunity to fly and others the opportunity to fly more often and this, in turn, has resulted in a normalization of travel by air. The carriers serve both the business and leisure markets with an estimated split of 30 percent to 70 percent between these two sectors. With respect to leisure, these operators serve a number of areas of demand, in Europe, for example, enabling travel such as visiting friends and relatives (VFR), people going abroad for winter sun, those with second homes, and those traveling to celebrate bachelor or bachelorette parties.

The apparent rising propensity to travel raises the issue of harmful carbon emissions related to such passenger movement. In response, carbon offsetting has been seen as a way of assuaging some of

such concerns. IATA describes this approach as a way for airline passengers and corporate customers to “neutralize” their proportion of an aircraft’s carbon emissions on a particular journey by investing in carbon reduction projects. It sees carbon offsetting as an immediate, direct, and pragmatic means to encourage action to limit climate change impacts, at least in the short term.

Another area of concern that has arisen concomitantly with increased air traffic volumes is the greater possibility of air rage incidences. In 2000, such an incident aboard a Southwest Airlines flight resulted in the death by suffocation of a disruptive 19-year-old passenger. It has been reported that since September 11, 2001, there have been a greater number of air rage incidents, resulting in headlines such as “Drunken Air Rage Granny Punched Passenger in Face After He Asked Her to Be Quiet” and “Air Rage Briton Pictured With Black Eye After Offering to Fight Everyone on Board Holiday Jet.”

As demand for air travel continues to grow, capacity constraints at airports will become increasingly important. One geographic area that is already severely constrained is London. The two main airports, Heathrow and Gatwick, are highly constrained, and there is a need for expansion of available capacity if further traffic growth to meet demand is to be facilitated. Yet, locating new infrastructure such as runways in the southeast of England is highly contentious due to public concerns about noise, pollution, and associated road infrastructure development. As people continue to want to fly, similar debates will become more prevalent worldwide, particularly in largely urbanized destinations with physical limitations on potential for capacity expansion.

International Customs and Duties

In 136 C.E., Palmyra, an ancient oasis city in the central Syrian Desert, levied one of the first customs tariffs on record, outlining tax rates for commodities being imported through Palmyra for the Roman Empire. Emperor Hadrianus assigned Palmyra the role of collecting municipal customs duties, and the tariff documentation was engraved on a stone pillar in Greek and Aramaic. Salted goods carried by donkey were assessed “three denarii per load at importation and exportation.”

Throughout centuries of human history, nations have initiated and attempted to control trade because of its economic importance. Unlike many taxes, customs duties on imports and exports were easy to collect, and they became one of the most reliable sources of public revenue. In the modern-day era of globalization, nations have banded together and created international and national customs and trade associations to classify imported and exported goods and manage and regulate customs duties. Besides customs agreements with other countries, individual nations operate their own customs agencies to establish and enforce customs laws. Travelers entering and leaving a country with merchandise must negotiate a patchwork of customs regulations, but the trend seems to be moving in the direction of customs and duty globalization to match trade globalization.

World Customs Organization

Headquartered in Brussels, Belgium, the World Customs Organization (WCO) has gained worldwide recognition for its development, promotion, and implementation of modern customs and procedures. The WCO maintains the international Harmonized System (HS) of goods classification and administers the technical aspects of the World Trade Organization (WTO), Agreements on

Customs Valuation, and Rules of Origin. In the 21st century, WCO members are responsible for customs controls on more than 98 percent of all international trade.

The WCO has created a number of customs systems to achieve its objectives. In 1988, the International Convention on the Harmonized Commodity Description and Coding System (HS Convention) was adopted as a system of naming and compiling international trade statistics. It has a database of about 5,000 commodity groups arranged in a legal and logical structure with rules to achieve uniform classification. The HS Convention is also used for other customs purposes, including monitoring controlled goods, internal taxes, freight tariffs, and economic research and analysis.

Implemented in 2006, the International Convention on the Simplification and Harmonization of Customs procedures, the revised Kyoto Convention (or RKC)—not to be confused with the United Nations Kyoto Protocol on Climate Change—is composed of several key governing customs principles. Some of the principles include transparency and predictability of customs controls, standardization and simplification of the goods declaration and supporting documents, maximum use of information technology, and minimum necessary customs control to ensure compliance with regulations.

Both the ATA Convention (the term *ATA* is a combination of the initial letters of the French words *admission temporaire*) and the Istanbul Convention are arms of the WCO governing temporary admission of goods. The ATA system, integral to both conventions, allows goods to freely move across frontiers and temporarily admits them into a customs territory with duties and tax relief. A single document called the ATA Carnet secured by an international guarantee system covers the goods.

The Arusha Declaration on Customs Integrity is a nonbinding document that elucidates basic principles to promote integrity and fight corruption within customs administrations.

Adopted in 2005, the SAFE Framework of Standards to Secure and Facilitate Global Trade is a nonbinding agreement setting supply chain security and facilitation standards for goods being traded internationally and champions the seamless movement of goods through secure international trade supply chains.

Federation of International Trade Associations

Founded in 1984, the Federation of International Trade Associations (FITA) encourages international trade by strengthening the role of local, regional, and national associations with an international mission throughout the United States, Mexico, and Canada. The FITA's 450 members and 450,000 linked company members are dedicated to promoting international trade, import-export, and international finance. Members include freight forwarders, airlines, shipping companies, port authorities, trading companies, and telecommunications companies.

The Tariffs and Customs section of the FITA Web site features tariff rates for the 21 members of the Asia Pacific Economic Cooperation Tariff Database and AsiaCalculator, a search engine that figures the applicable customs duty for imports from Asia. It lists China Import Tariffs, customs information for over 100 countries, global tariffs for the United States, Canada, Mexico, and European Union (EU) tariff schedules, customs information about Russia, and information about Swiss customs.

European Customs Union

Countries have banded together to facilitate trade and navigation customs on the national level as well. In July 1968, Belgium, France, Germany, Italy, Luxembourg, and the Netherlands solidified the founding of a customs union planned under the 1957 Treaty of Rome. Though the European Customs Union and the European Union rules include caveats that there be no customs duties at borders among EU member states, there are common customs duties on imports from outside the EU and common rules of origin for products from outside the EU apply. There is a common definition of customs value.

All member states of the European Union form a customs territory, the European Customs Union, where unified customs arrangements apply. When goods are imported into the EU countries, they are covered by EU-wide customs, tariffs, and customs procedures, but once goods have been imported and duties paid, no more duties may be charged even if the goods cross the borders of member states.

Eurasian Economic Union

The heads of Russia, Belarus, and Kazakhstan laid the foundation for a Eurasian Economic Union in

spring 2013, using the European Union as a model. They said that the agreement on the Eurasian Economic Union would be based on a code of laws, more than 70 agreements. Combining all of the laws would be the basis of an economic union. The three countries also discussed rules for allowing other formerly Soviet countries to join the existing customs union between Kazakhstan, Russia, and Belarus.

Southern African Customs Union

An alliance between South Africa, Botswana, Lesotho, Namibia, and Swaziland, the Southern African Customs Union (SACU) is one of the oldest customs unions in the world, established in 1910 as a Customs Union Agreement between what was then the Union of South Africa and the High Commission Territories of Bechuanaland, Basutoland, and Swaziland. The union went through some evolutions and country renaming to reach its present configuration.

The five member countries of SACU apply the same rates of duties on imported and locally manufactured goods, and all customs and excise taxes are paid into South Africa's national Revenue Fund to be shared among members according to a revenue-sharing formula. South Africa also has customs agreements with other countries including France, the Netherlands, the United Kingdom, and the United States.

Mercosur

Argentina, Brazil, Paraguay, and Uruguay are members of Mercosur, the Common Market of the South. Argentina, Brazil, Uruguay, and Paraguay founded the Mercosur customs union in 1991, with Bolivia, Chile, Colombia, Peru, and Ecuador participating as associate members. The goal of Mercosur is to streamline import and export duties as much as possible while allowing members to keep their autonomy.

Being part of Mercosur is both a positive and a negative experience for countries belonging to the customs union. For example, Mercosur states charge 20 percent duty on any automobile imports and 11 percent on raw material imports. Argentinian import duties begin with Mercosur rates. In addition to Mercosur tariffs, Argentina imposes value added taxes (VATs) to imports that are divided into two types: simple imports and goods imported specifically for resale. Argentina taxes simple imports at 21 percent, or 10.5 percent for specific industries

like steel or petrochemicals. Goods imported for resale are taxed at 10.5 percent and 5.5 percent to stimulate economic growth.

Protectionist rules within Mercosur frequently cause disagreements. In early 2013, Argentina and Brazil levied nonautomatic import licenses on a variety of goods that they trade back and forth, angering industrialists on both sides of their common border. Business leaders from Uruguay complained for months that Argentina blocks imports from their country.

North American Free Trade Agreement

Because of their common borders, the United States and Canada and the United States and Mexico have historically negotiated trade agreements, but the North American Free Trade Agreement (NAFTA) superseded them all. On January 1, 1994, Mexico, the United States, and Canada, entered into the NAFTA customs agreement, which removed barriers to trade and investment between the United States, Canada, and Mexico. NAFTA created one of the world's largest free trade zones and built the foundations for strong economic growth and rising prosperity for Canada, the United States, and Mexico.

NAFTA eliminated all nontariff barriers to agricultural trade between the United States and Mexico; many tariffs were eliminated immediately while others were phased out over periods of five to 15 years. Mexico and Canada reached a separate bilateral NAFTA agreement about market access for agricultural products, eliminating most tariffs either immediately or over five, 10, or 15 years. The two countries maintained tariffs affecting trade in dairy, poultry, eggs, and sugar.

In 2012, NAFTA had a combined output of \$17 trillion across North America, with the most popular exports from Canada to the United States including mineral oil, fuel, motor vehicles, machinery, wood, and electrical machinery. NAFTA helped provide Canadian businesses with better access to materials, technologies, investment capital, and talent across the rest of North America, giving Canadian businesses a competitive advantage compared to suppliers who did not belong to NAFTA.

As part of the free trade agreement, Canada, the United States, and Mexico enjoy favorable if not duty-free terms of trade, but customs agencies require a certificate of origin to confirm that a product was made in a NAFTA country before it can be

classified as duty free. This enables customs officials to quickly decide which goods qualify for preferential tariffs and which require only minimum processing. Another requirement is to clearly outline the origin of the raw materials in a product. Failure to do this puts businesses at risk of being charged a penalty and of the goods being charged duty at a later time, duty that could be up to 20 percent of the value of the goods.

Trade between the United States and its NAFTA partners has soared since the agreement took effect. The United States had \$918 billion in total (two-way) goods trade with Canada and Mexico during 2010. Goods exports totaled \$412 billion and goods imports totaled \$506 billion.

International Rail Transit

Over the next four decades, global passenger and freight travel is expected to reach double the 2010 levels. Depending on the scenario used to evaluate present data, the transport sector's energy consumption and emissions are projected to increase from 40 to 80 percent by 2050. Growth in global transportation will have consequences far beyond energy and emissions through the course of this expansion.

Infrastructure for the surface transport sector must increase significantly to 2050, as global mobility surges. Various analyses show that it is expected that the world will need to add nearly 208,000 miles (335,000 kilometers) of rail track and 15.5 million miles (25 million kilometers) of paved roadway, a 60 percent increase over 2010 combined rail and road network length by 2050.

Regional Impacts

Nonmembers of the Organisation for Economic Co-operation and Development (OECD) regions will account for nearly 90 percent of global travel increases. The largest expected infrastructural additions will be in rapidly emerging economies, such as China and India. Southeast Asian nations, Latin America, and the Middle East are also expected to contribute considerable land transport infrastructure between now and 2050. By 2050, non-OECD transport infrastructure investment and maintenance spending levels are anticipated to be nearly 20 percent higher than in OECD countries.

Although many parts of the world experienced a recession over the past decade, global average per capita gross domestic product (GDP) increased (in real U.S. dollars), with average per capita GDP in regions such as China, India, southeast Asia and eastern Europe more than doubling. This growth in wealth has contributed to a demand for mobility, both in terms of passenger travel and in movement of freight. Surface travel increased by 40 percent in one decade, and Asia and the Pacific, in particular, accounted for more than half of that growth.

Many countries in Europe and Asia have embraced effective policies and invested significant funds in their rail and transit sectors, especially for intercity passenger rail. (The United States currently lags far behind global competitors in terms of expenditure relative to population.) Some of the nations that have invested

the most in rail infrastructure are (in descending order from \$12.50 to \$0.20 per \$1,000 GDP, 2008): China, Switzerland, Austria, India, United Kingdom, Spain, Netherlands, Sweden, Russia, France, Italy, Germany, United States, and Turkey. It was expected that the stimulus funds under the American Recovery and Reinvestment Act of 2009 (ARRA) would substantially increase the U.S. amounts invested in rail transit.

Car Comparison

Transit patronage in the United States is now 23 percent higher than in 1993 and growing faster than car usage. The growth has been particularly strong since about 2003 and has continued since 2008. There seems to be a resurgence in the United States in the popularity of utilizing mass transportation modes. All of the growth in ridership since 1993 has been on rail-based modes.

Rail modes have increased their shares of total patronage, particularly heavy rail, from about 25 percent to 35 percent of the total. (Bus share has significantly declined from 65 percent to 50 percent.) The patronage on light rail has increase rapidly from a relatively small base of 168 million users to 481 million users over the same period.

The century-old growth of automobile use in metropolitan areas appears to have plateaued and even declined across the world's developed cities. European cities historically have built more infrastructure to accommodate more cycles and transit systems and are less dependent on the automobile. Compared with the United States, European governments have made a serious commitment to rail and transit investments. This is reflected in the region's more extensive and denser networks, as well as its more balanced modal split. (About 16 percent of all European passenger travel is undertaken by bus and rail, compared with a mere 4 percent in the United States.)

The cities in Asia and the Middle East have also invested large amounts of capital in mass transportation infrastructure. In the face of challenges such as high gasoline prices, traffic congestion, and carbon emissions, public transportation offers a range of benefits over private automobile travel.

Rail ridership is on the rise in many countries. With many new systems under construction or in the planning stages, orders for rail vehicles are expected to show strong growth in the coming

years—and these orders will translate into employment growth.

Much of the current ambition is directed toward the expansion of intercity high-speed rail (HSR) lines. In 2009, HSR lines totaling some 6,650 miles (10,700 kilometers) worldwide were operational. In 2008, the world's HSR fleet consisted of some 2,200 trains. The vast majority of these were in western Europe, followed by Asia, with most of them in Japan. Listed in order of their national track-building projections between now and 2025, the front runners include China, Spain, France, Japan, Turkey, Germany, Italy, Poland, Portugal, the United States, Sweden, Morocco, Russia, Saudi Arabia, Brazil, India, Iran, South Korea, Argentina, Belgium, the Netherlands, the United Kingdom, and Switzerland.

Major Markets

Currently, the leading global rail manufacturers are Bombardier of Canada, Alstom of France, and Siemens of Germany, but they are increasingly challenged by China's China South Locomotive and Rolling Stock (CSR) and China Northern Locomotive and Rolling Stock (CNR). Smaller but significant manufacturers include Ansaldo-Breda of Italy, CAF (Construcciones y Auxiliar de Ferrocarriles) and Talgo of Spain, Stadler of Switzerland, and Hyundai Rotem of South Korea. (Japanese competitors are part of large industrial conglomerates.) Four nations that have retained significant manufacturing employment in the rail and transit industries, and are also global leaders in rail transit growth, are Germany, Spain, Japan, and China.

Germany is one of the largest rail and transit markets in the world. Its rail manufacturing industry is a global technology leader; it has strong internal demand and even larger export sales. Germany's per capita investments in rail and transit are double those of the United States. However, rail advocacy groups argue that the German government is not investing enough in rail infrastructure. A comprehensive joint assessment by rail operators and rail manufacturers likewise concluded that intercity and urban rail investments of about \$9.3 billion per year are needed from 2008 through 2015 to keep pace with ridership.

Spain maintains the largest high-speed rail construction program in Europe. Its rail travel increased 55 percent between 1990 and 2008, far

outstripping its population growth. The government's 2004 Strategic Plan for Infrastructures and Transport (PEIT) still serves as a powerful planning tool, and the two-year Extraordinary Infrastructure Plan of April 2010 allocates 70 percent of the country's \$24 billion in transportation funds to rail. The HSR network of Spain has surpassed Germany's in length and in 2009 was second only to France's in all of Europe.

Japan was the first nation to implement high-speed rail development (in 1964) and continues to be a global leader. Japan has developed a strong capacity for the operation of high-quality rail service. Though the country's population rate is declining, rail ridership remains relatively high. Japanese train manufacturers are looking increasingly to the global market; their exports accounted for more than one-third of their revenues over the past decade.

China's leadership has embraced a highly ambitious plan to expand the country's intercity rail network, possibly reaching 93,000 miles (150,000 kilometers) by 2020, including 16,000 miles (26,000 kilometers) of high-speed lines. China is expected to account for more than half of global rail equipment expenditures in coming years. The country's two dominant rail manufacturing companies, CSR and CNR, together employ more than 200,000 people directly.

When it comes to rail and transit, the United States has not had a coordinated infrastructure investment and industry development policy for several decades. Meanwhile, China's focus on appropriating and absorbing foreign technology has been spectacularly successful to date. The country's decision makers have been aggressive about using their huge market as a lure for foreign companies. The United States offers a potentially huge market—assuming that, like China, it is willing to prioritize rail and transit investments.

International Travel

The United Nations World Tourism Organization (UNWTO) reports that in 2012, for the first time, 1 billion people traveled across their national borders—a comprehensive demonstration that there is an ever-increasing desire and propensity to travel farther from home and between different countries. The UNWTO states that globally, as an export category, tourism ranks fourth after fuels, chemicals, and automotive products. Lifestyle changes, increased personal affluence, and migration are some of the key factors that have resulted in this upward movement in demand for international travel. This greater individual mobility has also been matched by increases in accessibility of modes such as air for more people, largely associated with the rise in low-cost carriers, their affordability, and the greater connectivity they provide to a variety of destinations.

UNWTO figures also suggest that just over half of all tourists in 2012 were from Europe, while one-fifth came from Asia/Pacific and another fifth from the Americas. In addition, these statistics show that people tend to choose these three regions as their destinations and that half travel for leisure, a quarter for visiting friends and relatives (VFR), and 15 percent for business purposes. In order to demonstrate the economic dimensions of such travel, the U.S. Travel Association reports that \$244.16 billion is spent each year for business travel, an amount that represents one-third of total U.S. travel spending.

While air may be the leading mode for international travel, such movement is also undertaken using a number of other modes: coach, rail, maritime, and even foot (for some of those who venture to cross borders between states, either as a leisure activity or to try to access better life opportunities in another country). However, most of the international travel that takes place tends to be dominated by air transport, a mode that enables greater distances to be traversed more quickly than other options. Business travelers rely heavily upon the mode to enable economic connectivity across a networked, global marketplace.

Taking another viewpoint, air travel is important to the maintenance of social and cultural links between people at home and those located overseas in the diaspora (people who are living away from their homelands). For these people, air transport links provide a bond that facilitates the construction of transnational identity and citizenship and can serve to maintain social networks and intensify personal association with “home,” however distant it may be temporally or geographically. In addition, air transport plays an important role in another sector: it is equally valuable to people who wish to visit other countries during their leisure time.

Travel motivation appears to be fundamentally focused on a desire to maximize one’s own well-being or satisfaction. Concentrating on international leisure travel and briefly considering the variety of people’s motivations to visit particular destinations reveals the true scope of desire for international travel. This list indicates some of the diversity of activities in which people may wish to participate, which would, in turn, determine their chosen destination:

- Specific religious, pilgrimage, and other holy activities such as visits to the Vatican and attending the Haaj
- Extreme sports and other risky activities such as bungee jumping and paragliding in New Zealand, scuba diving in Greece, or skiing and snowboarding in Switzerland or the United States
- Sun seeking (sometimes described as sun, sea, sex, and sand travel) in destinations such as the Caribbean and southern countries of Europe
- Visiting historic sites such as Machu Picchu in Peru or the Taj Mahal in India
- Scientific travel to places such as Antarctica
- Cultural travel and making connections between migrant families
- Medical tourism, wherein people travel to access medical care unavailable at home
- Young adult travel such as gap year, backpacking, spring break

At the same time, the rising economic prosperity of countries such as Brazil, Russia, India, and China (the BRIC countries) and a concomitant emerging middle class has resulted in a related increase in international travel from these origins. Projections suggest that these and other similar countries will continue to be important drivers of travel abroad. International travel patterns change with time: for example, where once travelers may have been mainly attracted to historical and cultural sites, there are now also concurrent movements of people seeking to purchase key brands in chosen cities, that is, the expansion of shopping travel and pursuit of brands in destinations such as Paris, London, and New York by visitors from origins such as China, Russia, and South Africa. Similarly, Indian travelers may also visit souks, bazaars, and shops in the Middle East for gold.

International air travel operates within an international and national framework made up of policies, procedures, and processes working together to maintain a smooth and safe operation of the industry. Such structures are formulated with social, economic, and environmental objectives at their fore, as well as taking account of regulatory/deregulatory and legal constructions that provide parameters for the operation of the transport mode at national and international levels. Other modes also operate within defined structural frameworks, although these are less complex and restrictive than those for aviation. Within a primary focus upon social issues around international travel in this article, greater exploration of these organizational models is less important here than simply allowing that they exist as a background and facilitator of all the activity described herein.

Nevertheless, while all social and economic indicators suggest that demand for international travel appears likely to continue, there are concerns about

the capacity for infrastructure, such as runways and terminals, to meet such requirements. Looking specifically at aviation, there is increasing awareness of the impacts of airports on surrounding communities and environmental and other land-related limitations on further airport expansion to supply the projected demand. This raises the issue of sustainability of international travel, with ideas around this theme being regularly discussed in contemporary air transport and tourism discourse. Nevertheless, in terms of local communities, there can be large-scale benefits of international travel. The World Bank indicates that tourism entails investments in public works: roads, water and sewage systems, hospitals, communications, and transport systems that will not only attract hotel and tour operators but can also provide people living in the area with improved resources and services.

However, there is little doubt that air travel impacts on the environment. It enables people to travel much greater distances and, thus, means that their travel is associated with a greater contribution to greenhouse gas production than local travel would have been. The aircraft themselves are also larger scale producers of emissions than those related to other modes and this, in turn, contributes to increased carbon monoxide in the atmosphere, leading to potential climate change effects. There are also important noise considerations in proximity to airports, resulting in curfews and flight path restrictions implemented to assuage effects on local communities.

High Speed Rail

A potential solution to these sustainability concerns may be found in high speed rail (HSR). For example, in Europe, as concerns rise about environmental effects of air transport, there have been political and practitioner suggestions that high speed train (HST) services could result in modal shift (movement of passengers from the use of aviation to rail). However, the extent to which rail can yet compete with air is less clear. While it has been reported that, on routes between city pairs such as Paris and Brussels, improvements in rail journey times have resulted in a decrease in demand for air services on the route, it seems that low-cost carriers continue to dominate the European market in general. Travel time is an important factor in passenger choice of mode, and this is likely to be one of the main areas in which air travel continues to have the advantage

in Europe. In addition, Boeing reports that in 2010, worldwide railways carried 45 percent less passenger traffic than commercial aviation and that the total distance covered by railway networks was 2.5 percent that of the aviation network. The aircraft manufacturer goes on to state that data analysis suggests that rail is suited for carrying passengers over relatively short distances.

Notwithstanding these findings, there are some international rail journeys that have existed for many years and, in contrast to many other aspects of passenger transport use, demand for these trips appears to be for the actual travel experience rather than the more traditional perception that travel is a derived demand, that is, it is something that is undertaken as part of a desire to satisfy another need (that of arriving at the chosen destination). Examples of such services are the Trans-Siberian Express, Rovos Rail Pride of Africa, and the Venice Simplon–Orient Express, where transport itself forms a main part of the focus of the journey.

Ocean Cruising

Cruising is another example. It is one of the fastest growing sectors of the international travel market. For example, the United Kingdom–based Passenger Shipping Association reports that UK ports are projected to handle 1 million cruise passenger embarkations in 2013 and that more passengers than ever embarked and called at British ports in 2012, with cruising accounting for one in every eight of all package holidays taken. In addition, there has been an accompanying expansion in the available passenger capacity worldwide (with 13 ships with 14,886 new beds launched in 2011). The entire experience onboard, as well as the idea of visiting other countries, appears to attract people to take this type of vacation. Importantly, lowering of fares has led to a larger pool of people being able to afford to go on a cruise. Traditionally, this type of travel was seen as safe and leisurely. Nevertheless, the social impacts of this industry are also relevant to the discussion of international travel here. Labor exploitation of those who work onboard, commercialization and congestion of ports, and environmental impacts on destinations are some of the issues that are of concern. In addition, there have been recent headlines about cruise ship safety issues, such as breakdowns and fires, that have brought the models of operation of the industry into focus.

Looking briefly at some of the ethical issues around cruise ship operation illustrates further the multifaceted nature of international travel. Cruise ships are staffed by people from a diversity of ethnicities and cultures who live in close proximity on lower decks of the vessels and work long hours to ensure the successful operation of all the upper-deck activities. The economic disparity between the crew and the passengers is just one feature of the close interaction between staff and customers and the moral discomfort it can potentially engender.

Expanding on the topic of ethical concerns around travel in general leads to consideration of issues related to the impact of tourists on traditional cultures, practices, and lifestyles. International travel has enabled access to a number of destinations whose popularity means they can be overrun by tourists at certain times of the year. Thinking first of impact on social activity in an urban space and considering a destination such as Edinburgh in the UK in the summer when the castle, festival, and general tourist attractiveness can mean the place is so busy with visitors that local people can find it hard to go about their own business easily in the city. At the other end of the development spectrum, a small island such as St. Vincent in the Grenadines may be highly dependent upon tourism economically, but it may also experience being overwhelmed by tourist flows, with net effects upon the ways in which people adapt their lifestyles and practices to satisfy the needs of the visitor. For example, sex tourism and all its attendant accoutrements have been features of Caribbean tourism as the region's dependency upon the industry has developed. This raises ethical and moral considerations for local people and cultures. Thus, while economic benefits are undoubtedly being funneled into the local business environment, the social impacts may not all be as beneficial as may be thought initially.

Information Availability

One of the most important attributes of contemporary international travel is the wide range of resources that are available for considering options for travel and then booking that travel. The information and communications technology (ICT) revolution continues to fuel the availability of media for purchasing travel, and this disintermediation (essentially, the removal of the middleman—travel agents, in this case) has meant that people have had greater access

to international transport information and, thereby, been able to make bookings more easily and, with increasingly portable devices, on the go.

Virtual Mobility

Despite the rise in tools that facilitate communication across spatial distance such as Skype and videoconferencing, business travelers still appear to prefer face-to-face contact afforded by travel. Such movement is seen to deepen interpersonal relationships within the organization and with clients. However, research conducted with business travelers by Ipsos MORI for Tandberg in 2006 revealed that motivations for business travel may be rather more multifaceted: over half of European travelers admitted that some of their business trips were unnecessary to their work. Furthermore, 69 percent of those surveyed stated that the enjoyment of experiencing new cultures was the highest rated benefit of business travel, compared to 47 percent who said getting face-to-face with clients was what they enjoyed. Significantly, 15 percent of travelers confided that business travel in fact made them less productive in their jobs. These findings point to the potential for organizations to exploit the ever-evolving non-travel-based communication tools further to meet business objectives more effectively and financially efficiently.

Perceived Risk

Researchers Andrew Lepp and Heather Gibson (2003) have identified seven domains of risk that can affect people's international travel choices: health, political instability, terrorism, strange food, cultural barriers, a nation's political and religious dogma, and crime. Exploring a couple of these further illustrates the insidious ways in which ideas around risk can impact travel behavior.

Security concerns about terrorism, political instability, and crime have increasingly come to the fore with, for example, a recent rise in kidnappings and killings of foreign workers in some African states. This has led to developments such as "no-fly" databases that seek to ensure that all passengers who travel by air are of no risk to other travelers and the aircraft itself and services such as niche security companies for travelers to less developed and greater risk countries. In addition, since September 11, 2001, there has been recognition that aircraft can be used as a weapon for attack on those on the ground.

Public Health Security and Disease

While increased accessibility across nations has enabled the exchange of cultural and social values, there has also been spread of disease associated with such travel. As mobility has provided opportunities, it has also been an enabler of movement of vectors for illness that has seen associated dispersion of illnesses such as SARS, flu, dengue fever, tuberculosis, and malaria across nations and continents. This globalization of health concerns is one of the main drawbacks of travel that crosses national borders. For example, there have been reports that there is an increased incidence of HIV along some of the main international road routes in parts of Africa with evidence suggesting that long-distance drivers may engage in unsafe behaviors facilitating the transfer of the virus. Similarly, the World Bank suggests that seafarers, airline crews, and infrastructure construction workers may also be significant to such spread.

Another transport-related risk to international travelers relates to the incidence of road accidents abroad and the involvement of tourists in accidents. For example, the *New Zealand Herald* reports that in 2012, three American tourists were killed in a crash in May, and four Argentines died in a head-on crash in July. These were among 15 fatal accidents involving foreign drivers that year, which comprised around 7 percent of the total number of fatal crashes. The worldwide road fatality statistics are also relevant to this discussion. Allianz has compiled statistics that show, in absolute numbers the countries that, respectively, have the highest risk of death from road accidents: (1) India, (2) China, (3) United States, (4) Russia, (5) Brazil, (6) Iran, (7) Mexico, (8) Indonesia, (9) South Africa, and (10) Egypt. Many of these are key tourist destinations, highlighting an often overlooked risk of international travel.

International Waters

International waters can be classified as waters to which more than one nation has rights. These include oceans and seas with international rights of passage or use, lakes, and inland seas with access by more than one nation, rivers and waterways that have more than one riparian nation (transboundary rivers), and transboundary groundwater resources.

Oceans and seas with international rights of passage or use are primarily defined by the United Nations (UN) Convention on the Law of the Sea (UNCLOS). Historically, a nation's waters were limited to what it could effectively control and all others were effectively international waters. This effective control varied with a state's naval power and its ability to control coastal water from shore. Hugo Grotius described this as he laid the foundations of international law based on natural law, and specifically developed the theory of international waters in *The Free Sea (Mare Liberum)* in 1609. Thus, by the 17th century the concept of freedom of the seas was established in theory.

This legal theory was then expanded by the Dutch jurist and legal theorist Cornelius van Bynkershoek in the 18th century. Coastal nations were assumed to have the right to waters up to three nautical miles from the coast (cannon-shot range of the most advanced cannon at the time as calculated by the Italian, Ferdinand Galiani). The concept and limit held except in times of war or by international treaty until the 20th century, when nations argued for rights to the resources found off their coasts.

UNCLOS evolved through a series of negotiations resulting in the first UN Conference on the Law of the Sea, which took place in 1956, and continuing through November 16, 1994, when the agreement entered into force. Negotiations continue to ensure the agreement addresses outstanding and emerging issues.

In *Economic Foundations of the Law of the Sea* (2009), Eric Posner and Alan Sykes point out that UNCLOS has a plausible economic logic:

Jurisdiction over portions of the ocean is assigned to states which can regulate them most cheaply and value them the most. These jurisdictional rights are subject to limits that reflect the interests of other states in navigation and other uses of the seas. For the vast areas of the ocean that no state can regulate, the convention provides for an open access regime subject to simple rules, mostly self-enforcing, to limit conflict over resources.

Thus, UNCLOS divides the seas into zones. Starting with the land, the baseline is drawn at the mean low-water mark and around internal waters. Within this area the nation is the ultimate sovereign and no other nation has rights, even for navigation.

Territorial sea then extends from the baseline seaward for 12 nautical miles. The coastal state may establish laws, use any resource, and regulate the use of resources therein. International vessels have the right of innocent passage and military vessels have the right of transit passage. The contiguous zone extends an additional 12 nautical miles. There the coastal state may exercise the control necessary to prevent the following:

. . . infringement of its customs, fiscal, immigration, or sanitary laws and regulations within its territory or territorial sea; [and] punish infringement of the above laws and regulations committed within its territory or territorial sea.

The exclusive economic zone (EEZ) extends from the edge of the territorial sea to 200 nautical miles from the baseline. Within this zone the coastal state has exclusive rights to exploit all resources. Foreign nations maintain the right of transit or overflight subject to the coastal state's regulations.

The continental shelf is defined geologically and bathymetrically. Where it goes beyond the EEZ, it extends the coastal state's sovereign rights for the following purposes:

. . . for the purpose of exploring it and exploiting . . . the mineral and other nonliving resources of the seabed and subsoil together with living organisms . . . which, at the harvestable stage,

either are immobile on or under the seabed or are unable to move except in constant physical contact with the seabed or the subsoil.

The coastal state's rights may not exceed 350 nautical miles from the baseline even if the continental shelf extends beyond. Foreign nations have rights to navigation, fishing, laying undersea cables, overflights, and research within the limits of other international agreements.

High seas are those areas not falling into one of the other zones, and all nations have freedom of navigation, overflight, lay submarine cables and pipelines, construct artificial islands or other installations permitted by international law, fishing subject to other parts of UNCLOS or other international law, and scientific research.

UNCLOS also addresses the rights of nations to resources and passage under such topics as straits used for international navigation, archipelagic states, islands, enclosed or semienclosed seas, the rights of land-locked states, access and rights to resources, environmental quality, scientific research, the resolution of disputes, and others.

UNCLOS is the primary international legal agreement dealing with international ocean and sea waters. While each U.S. president since the inception of UNCLOS has encouraged its ratification, Congress has not done so. Numerous other bilateral and multilateral agreements exist to address specific issues among specific nations in specific areas.

Inland Waters

Lakes and inland seas accessed by more than one nation are another form of international waters. Enclosed or semienclosed seas are addressed by UNCLOS. These are defined as the following:

. . . a gulf, basin or sea surrounded by two or more States and connected to another sea or the ocean by a narrow outlet or consisting entirely or primarily of the territorial seas and exclusive economic zones of two or more coastal States.

In those situations, coastal states shall work directly with each other or through the appropriate regional organizations to do the following:

. . . coordinate the management, conservation, exploration and exploitation of the living

resources of the sea . . . the implementation of their rights and duties with respect to the protection and preservation of the marine environment . . . their scientific research policies and undertake where appropriate joint programmes . . . [and] to invite . . . other interested States or international organizations to cooperate with them . . .

In other instances of inland water bodies, the management of the international waters is by agreement between the coastal states and may pre-date UNCLOS. For international freshwater bodies there is no overall binding agreement as with oceans and seas. The agreements on conservation, development of resources, navigation, environmental maintenance and other sound use are codified in bilateral or multilateral agreements.

Rivers and waterways that have more than one riparian nation (transboundary rivers) include 263 river and lake basins that cover nearly half of the world's land area. One hundred forty-five nations include at least one international basin and 21 nations lie entirely within an international basin. The United Nations points out the following:

While most basins are shared between just two countries, there are many basins where this number is much higher. There are 13 basins worldwide that are shared between 5 and 8 riparian nations. Five basins, the Congo, Niger, Nile, Rhine and Zambezi, are shared between 9 and 11 countries. The river that flows through the most nations is the Danube, which travels within the territory of 18 nations.

For instance, throughout Europe and western Russia, rivers are connected into an international waterway suitable for navigation. In 1992, the Rhine–Main–Danube Shipping Canal was finally completed linking the North Sea to the Black Sea. In 2002 the Russian waterways became part of the European inland waterway network, thus connecting the Caspian Sea, Black Sea, Mediterranean Sea, Atlantic Ocean, North Sea, Baltic Sea, and Barents Sea by inland water routes. Not only is this inland water system an important engineering feat, it is a major feat of diplomacy and international and domestic policy linking nations physically, economically, and socially. A major problem, however, is that the route also transports invasive biotic species

throughout Europe and western Asia and is a route for chemical pollution transport as well.

Management of major international waters is usually coordinated through river basin commissions or other coordinating bodies such as those on the Nile River, Mekong River, or Saint Lawrence Seaway, and many others.

Groundwater Resources

Transboundary groundwater resources, while generally not navigable, are of major importance, particularly where irrigation is important or where ground water resources are abstracted for domestic consumption or other use requiring maintaining water quality. Like river basins, underground water bodies are not subject to political boundaries so often they are of concern to two or more nations that overlay or otherwise depend on the same resource. The two major concerns are pollution of the groundwater resource and over-abstraction by one nation depleting the water available to another overlaying nation. There is no global agreement pertaining to aquifer management, though principles have been established within the water management community for acceptable practices.

This issue will increase in importance as population grows and economic condition of the population increases, resulting in greater demand for higher quality, water-intensive foods, and demand for irrigation increases due to environmental changes and increasing food demand.

Intersections

Intersections are places on the roadways where two or more roads intersect. They are located on federal and state highways, country roads, and city streets. Intersections differ based on traffic control and on road design, but regardless of their differences, they were the sites of about 40 percent of the estimated 5,811,000 motor vehicle crashes that occurred in the United States in 2008. Between 1998 and 2007, 9,032 deaths each year, on average, were attributable to intersection crashes. These numbers are significant enough to make intersection safety a major priority for national, state, and local governments. The modern roundabout, a type of circular intersection, has been gaining popularity in the United States as an effective means of improving safety, traffic flow, and aesthetics.

Types of Intersections

Uncontrolled intersections are junctions without signs or traffic signals. Right-of-way belongs to the vehicle on the main road in three-way intersections, to the vehicle on the right in four-way intersections. Controlled intersections are marked by signals, traffic signs, or roundabouts. Despite the clarity of rules of the road governing controlled intersections, more accidents occur at these sites. According to a report from the National Highway Traffic Safety Administration (NHTSA), in an estimated

787,236 intersection-related crashes in 2008, about 52.5 percent (413,140) that were assigned a critical reason were traveling on roadways that were controlled by at least one traffic signal and 31.3 percent (246,385) by at least one stop sign.

The higher volume of traffic at controlled intersections is doubtless a contributing factor, but so is the number of drivers who are reckless or distracted. One study found that two of five drivers admitted to having run a red light within the past 30 days, and the 2008 NHTSA report found that in 96.1 percent of crashes the critical reasons were attributed to drivers. This includes 55.7 percent (438,194) drivers with recognition error (inattention, internal and external distractions, inadequate surveillance, etc.) and 29.2 percent (230,047) with decision errors (too fast for conditions or aggressive driving, false assumption of other's actions, illegal maneuver, and misjudgment of gap or other's speed).

Controlled intersections can present hazards for pedestrians and bicyclists too. Six percent of urban bicycle-motor vehicle collisions are related to these users not being able to finish crossing an intersection before the opposing traffic is released. Pedestrians—particularly children, the elderly, and the disabled—may also find it difficult to cross in the allotted time. The 2009 *National Manual on Uniform Traffic Devices* proposed a reduction from 4 feet per second, a common crossing time, to 2.8 feet per second.

Based on road design, the most common type of intersection is the four-way intersection where two roads cross. T-intersections occur when one road dead-ends into a through road. Generally, the minor road at a T-intersection is controlled by a stop sign that directs the driver to wait until the major road is clear before proceeding. A Y-intersection also has three legs, often appearing as if two roadways merge to form one. Such roads may be marked with stop signs on all roads. Occasionally, an intersection has five or more intersecting roads. A six-way intersection involves the crossing of three streets, most often two perpendicular streets and a diagonal street. More than six roads intersecting is rare. A roundabout is an intersection that merges traffic from multiple roadways into a circle. In the United States, traffic moves counterclockwise.

Safety Issues

Based on the Fatality Analysis Reporting System data, an estimated 2,307,000 crashes occurred at

intersections across the country in 2008. Among these, 7,421 were fatal crashes, and in 733,000 crashes, one or more occupants suffered injuries. About 36 percent of these crashes involved people turning or crossing an intersection. Left turns were particularly hazardous, accounting for more than one-fifth of crashes, compared to 1.2 percent of right-turning vehicles. Several studies have been conducted with an in-vehicle warning system for failure-to-obey (running a stop sign or stop light) violations that uses visual, auditory, and brake pulse cues to warn drivers. Participants who did not use the system made three times the did-not-stop errors that participants using the system made. The implications are particularly positive for drivers 65 and older, who are over-represented in intersection crashes and the fastest growing segment of the U.S. population.

Angle crashes at intersections, a particular problem at T-intersections, are among the most severe of intersection crashes. Often limited stopping-sight distance and/or driver failure to judge gaps in opposing traffic are identified as the cause of such crashes. A Colorado experiment installed continuous green T-intersections (CGT) at two rural T-intersections to reduce angle crashes due to left-turning traffic. In CGTs, the main line through traffic passed through without stopping (the top side of the T), obeying a continuous green signal. Dedicated acceleration and deceleration lanes provided for left-turning movements. Concrete median and pavement markings provided lane separation. The results were encouraging: a 96.8 percent reduction in angle crashes per year, a 70 percent reduction in injury crashes per year, and a 60 percent reduction in total crashes per year. Several states, including Colorado, Florida, Maryland, North Carolina, and South Carolina, have converted from fully signalized to continuous green T-intersections to improve safety.

Traffic Circles and Roundabouts

Traffic circles, which are circular intersections where traffic is forced to move around a central island in one direction, were popular in the United States in the first half of the 20th century. In some places, traffic entering the circle has the right-of-way; in others, entering traffic is required to yield. Either way can create delays and congestion. The first traffic circle in the United States may have been Columbus Circle in New York City, built in 1905. Washington, D.C., has more than two dozen. But high numbers of crashes

A sign warns drivers about the shape of an upcoming intersection in the city of Maribor, Slovenia, in 2013. In the United States, as many as 40 percent of all motor vehicle accidents take place at intersections.

and increased congestion had traffic circles falling into disfavor by the mid-1950s.

Modern roundabouts are also circular intersections, but they avoid the problems that led to the decline of traffic circles. The roundabout slows entering traffic and allows all the traffic to flow through the junction freely and safely. Entering vehicles must yield the right-of-way to vehicles already in the circle. Traffic signals are not used, and pedestrians cross the streets at marked crosswalks. Delays are about 50 percent of the average delay imposed by a traffic signal. Aesthetically pleasing, they also improve safety and efficiency for pedestrians, bicyclists, and motor vehicles. Roundabouts have been built in California, Colorado, Florida, Maryland, Missouri, Nevada, Ohio, and Vermont.

Interstate Commerce Commission

When the U.S. Constitution was written in 1787, the need for establishing guidelines for regulating commerce among the states was clearly in the minds of the nation's founders. Article 1, Section 8, which came to be known as the Commerce Clause, established the power of Congress in the field of interstate transportation by stating that the new national legislature should have the power "to regulate Commerce with foreign Nations, among the several states, and with Indian Tribes." It took another century, however, for Congress to pass the Interstate Commerce Act, which created the Interstate Commerce Commission (ICC) and established the right of the federal government to regulate the railroad industry. This action was designed to maintain fair pricing in both passenger and freight services. Congress further strengthened the powers of the ICC in the early 20th century, with passage of the Hepburn Act and the Mann–Elkins Act. In 1935, Congress passed the Motor Carrier Act, giving the ICC the right to regulate the trucking industry. Subsequently, the ICC was charged with regulating other aspects of interstate commerce, exercising

oversight over interstate bus lines, telephone companies, oil pipelines, freight forwarders, transportation brokers, and express agencies. During the 1970s and 1980s, the move toward deregulation of the transportation sector resulted in an erosion of ICC power. Congress officially abolished the agency in 1995 and transferred most of its responsibilities to the Department of Transportation (DOT).

History

When the Civil War ended in 1865, the United States entered the Industrial Revolution with a vengeance. Thus the time was ripe for the railroad companies to emphasize profits and growth as they increased operations and expanded westward. The railroads had already formed monopolies in their designated areas, but increased industrialization led them to become fiercely competitive. Because public feeling against railroads was so intense, in 1871 Illinois became the first state to try to rein in railroads by regulating their activities within the state. Other states followed suit.

Only Congress had the power to regulate commerce that crossed state boundaries, however. Thus, the Interstate Commerce Act of 1887 gave the Interstate Commerce Commission the right to ascertain that prices set by the railroads were equitable. The ICC was the first independent regulatory agency created in the United States, and it became a model for those that followed. The ICC was initially composed of five members appointed by the president of the United States and confirmed by the Senate. That number increased over time. In order to guarantee objectivity, ICC members were banned from holding any financial interests in the industries they regulated. Despite having considerable authority, the ICC was weakened by the fact that it lacked enforcement power.

In the early 20th century, Congress attempted to strengthen the Interstate Commerce Commission by passing the Hepburn Act of 1906, which allowed the ICC to change railroad rates if those rates had been proven to be unjust or unreasonable during public hearings. Four years later, passage of the Mann–Elkins Act transferred the burden of proof to railroad companies, forcing them to demonstrate the reasonableness of their rate plans. By the 1920s, however, the trend was toward returning authority to railroad companies. Nevertheless, passage of the Esch–Cummins Transportation Act of 1920 allowed the ICC to

oversee railroad mergers and mediate in labor disputes. During this same period, railroads began facing increased competition from trucking companies, which had a good deal more flexibility than railroads in establishing routes. By 1940, the ICC had been given the power to regulate commerce in every field of interstate transportation except aviation.

After the creation of the U.S. Department of Transportation in 1966, the new department took on responsibility for all transportation safety functions. In 1976, Congress passed the Railroad Revitalization and Regulatory Reform Act, which returned more autonomy to individual railroad companies. Trucking companies also gained autonomy in 1980 with passage of the Motor Carrier Act. The Staggers Rail Act of 1980 cemented the move toward deregulation and stripped the ICC of many of its powers. Passing Congress with bipartisan support, the Interstate Commerce Commission Termination Act of 1995 abolished the ICC and created the Surface Transportation Board within the DOT.

Civil Rights

By exercising its regulatory authority over the nation's interstate bus routes, the Interstate Commerce Commission played a major role in the civil rights movement. In 1954, African Americans won a major victory when the Supreme Court handed down the landmark decision in *Brown v. Board of Education* (347 U.S. 483), which mandated desegregation of public schools in the United States. Over the next few years, a series of court cases abolished the "separate but equal" doctrine that had allowed Jim Crow laws to flourish in the south and other areas. However, African Americans were still being discriminated against within the transportation sector. In 1960 in *Boynton v. Virginia* (364 U.S. 454), the Supreme Court held that discrimination on public buses was unconstitutional.

By 1961, membership on the ICC had expanded to 11 members. Ten of those members had been appointed by President Dwight Eisenhower, a conservative, and only one by President John Kennedy, a liberal. On September 22, 1961, the ICC surprisingly responded to a petition from Attorney General Robert Kennedy by unanimously banning discrimination on all interstate buses. Bus companies were ordered to post signs stating that seating was to be carried out "without regard to race, color, creed, or national origin by authority of the

Interstate Commerce Commission." (In 1963 the ICC mandated inclusion of that statement on all bus tickets sold for interstate routes.) The actions by the ICC had major implications for the Freedom Rides, which took place during the summer of 1961. These rides allowed interracial delegations of civil rights activists to test compliance with *Boynton*. Over the course of their bus ride from Washington, D.C., to New Orleans, Louisiana, Freedom Riders were met with violence in cities in Alabama and Mississippi, and the cause of states' rights served as a rallying cry for white protesters.

Closure

At the height of its power, the Interstate Commerce Commission boasted 2,000 employees and operated with an annual budget of \$82 million. After the deregulation that decimated its authority in the first two years of the 1980s, the number of employees dropped to only 400, and the budget was slashed to a mere \$40 million. On December 30, 1995, President Bill Clinton signed the Interstate Commerce Commission Termination Act, officially abolishing the ICC. However, Congress rejected an attempt to abolish the Department of Commerce. The ICC was thus relegated to history after 108 years of regulating interstate commerce.

Within the Department of Transportation, the Surface Transportation Board continues to exercise regulatory power over safety issues and labor disputes within the railroad and trucking industries. Other powers that once belonged to the ICC have been distributed among various departments within the DOT.

Interstate Highway System

The Federal Aid Highway Act of 1938 requested the Bureau of Public Roads (BPR) to compile a report on "superhighways." The report, submitted to Congress in April 1939, proposed a network of interregional highways with connections through and around cities. Section 7 of the Federal Aid Highway Act of 1944 authorized designation of a 40,000-mile (65,000-kilometer) "National System of Interstate Highways." These were the first steps in what became, as President Dwight Eisenhower asserted, legislation that transformed America. It was Eisenhower who took the decisive step on June 29, 1956, when he signed the Federal Aid Highway Act of 1956. Subsequent legislation over the next four decades extended and modified the original act, the same time frame required for the idea of an interstate highway system to be fully realized.

Congressional enthusiasm for the new highway system dimmed when the focus moved to funding. Public excitement was soon shadowed by political battles and social struggles, and activists of future generations would declare the system the bane of civic identity and environmental health. But the 45,012.5 miles of limited-access roads that Eisenhower's dream became would one day carry 21

percent of the country's traffic on 1 percent of its roads and make it possible for a trucker to drive from Seattle to Boston on a single interstate highway in just four days.

The Beginning of the Interstate System

Although it would informally become known simply as "the Interstate," the official name of the proposed system was "The National System of Interstate and Defense Highways." Final changes expanded the system to 41,000 miles (65,983 kilometers) and authorized \$25 billion to be made available in fiscal years 1957 through 1969. The share paid by the federal government would be 90 percent. The money was the sticking point in Congress—no one wanted to pay the bill. The Federal Aid Highway Act of 1956 did not win approval until Representative Hale Boggs (D-Louisiana) of the House Ways and Means Committee, at the suggestion of Secretary of the Treasury George Humphrey, proposed the creation of the Highway Trust Fund, modeled after the Social Security Trust Fund. Revenue from taxes on highway-user products would be credited to the highway fund for use exclusively on the interstate system and other federal-aid highway and bridge projects.

In July 1956, the Bureau of Public Roads (BPR) and the American Association of State Highway Officials (AASHO) collaborated on the design standards. They agreed that the system would consist of divided highways with four or more 12-foot (3.7-meter) lanes. Controlled access would be the rule, with any crossroads moving over or under the routes. All overpasses had to have a 16.5-foot vertical clearance above the freeway, although 14-foot overpasses were permissible within urban areas. This particular specification was included to enable military equipment to pass clearly below an overpass, a reminder that national defense was paramount in the minds of the system's designers. Although military equipment of this size is not commonly transported on the Interstate Highway System, the standard remains. The highways were designed for speeds of 50 miles per hour (mph; 80.5 kilometers per hour, km/h) in mountain terrain, 60 mph (96.6 km/h) in rolling terrain, and 70 mph (112.7 km/h) in flat terrain.

Construction for the AASHO road test, administered by the Highway Research Board, began in August 1956 in Ottawa, Illinois. Financing was provided by an array of agencies and organizations that

included state highway agencies, the BPR, the U.S. Department of Defense, the Automobile Manufacturers Association, the American Petroleum Institute, the American Institute of Steel Construction, foreign countries, and U.S. materials and transportation associations. The 7 miles (11.3 kilometers) of two-lane pavements consisted of 836 test sections in the form of six loops and a straight portion and including 16 short-span bridges. The Department of Defense provided drivers and heavy vehicles for the test traffic, which began operating on October 15, 1958. The road test concluded on November 30, 1960. The test data established the relationships for pavement structural designs based on expected loadings over the life of a pavement.

Before the end of 1956, the first sections of the new system were completed. Both Missouri and Kansas claim the distinction of being home to the first completed section. The Missouri State Highway Commission placed a sign on the Mark Twain Expressway portion of U.S. 40 (future I-70) in St. Charles County, where construction, which included 3.1 miles (5 kilometers) of bridging, grading, and concrete paving leading to a new bridge over the Missouri River, began on August 13. On November 14, 1956, highway officials held a ribbon-cutting ceremony and posted a sign proclaiming the concrete paving of an 8-mile (12.9-kilometer) section of U.S. 40 (I-70) outside Topeka to be the first project completed under the 1956 act.

One of the persistent criticisms aimed at the project throughout its history has been the “cookie-cutter” sameness of the construction. While the design standards were exact, engineers, particularly after the early years, worked with experts from other disciplines and citizens to address environmental and preservationist concerns. One example, the Papago Freeway in Phoenix—the final segment of transcontinental I-10 (Jacksonville, Florida, to Santa Monica, California)—first was to be an elevated highway soaring 10 stories above Phoenix’s Central Avenue. When the structure was opened on August 10, 1990, a below-ground tunnel topped by a long grassy strip called the Margaret T. Hance Park linked the communities on either side of the highway.

The two decades of controversy that delayed the Papago Freeway are indicative of the kinds of problems that had to be resolved before the Interstate Highway System could be completed. Engineers

and steel were sometimes in short supply in the early postwar years, but right-of-way acquisition and the costs of urban routes particularly were problems no one had anticipated. The country was in a recession by August 1957, with unemployment reaching 7 percent and corporate profits reduced by 25 percent by April 1958.

Congress passed the Federal Aid Highway Act of 1958, which increased interstate funding by \$800 million for fiscal years 1959–61 and included an emergency increase of \$400 million for the federal-aid systems in fiscal year 1959. Even with additional funds, by the end of the year, construction expenditures exceeded trust fund receipts. Some feared the collapse of the planned highway system, and congressional critics charged that the states were wasting taxpayers’ money. President Eisenhower requested a temporary 1.5-cent increase in the gas tax, but the Federal Aid Highway Act of 1959 added only a penny (increasing the tax to 4 cents a gallon) through June 1961. But the funding crisis paled in comparison to the battles that were beginning in cities across the nation.

Rebellion in the Cities

By the time Eisenhower left office in 1961, 25 percent of the system (10,440 miles) with a cost of more than \$10 billion was open to traffic, but communities had been destroyed and people displaced in the process. The original plans for the interstate system had largely bypassed major cities, including only short connectors to link cities to the bypass highways. But big-city mayors and business interests lobbied for urban interstate routes, which they saw as a means of revitalizing urban areas and improving property values and thus tax bases. The BPR released a plan late in 1955 that included highway designations for 100 urban areas.

Plans for large metropolitan areas typically included an inner belt road around downtown, an outer belt highway circling the suburbs, and one or more roads connecting the suburbs to the city’s center. The Federal Aid Highway Act of 1956 provided for 6,100 miles of interstate highways through the nation’s largest cities. Later amendments increased urban highways to 8,600 miles, more than one-fifth of the total system.

Eisenhower was convinced that including the city routes had sold the bill to Congress. Inner belts that went around downtown areas meant that

traffic in and out of the city no longer needed to move along city streets. Residential neighborhoods not displaced by the new roads were isolated from the downtown area. Outer belts made travel from surrounding areas into the city's center easy. Since these outlying areas generally offered relatively cheaper land in larger sections, "edge cities" or mid-town sections began to develop.

When the plans were drawn, often as far back as the 1940s, to replace deteriorating homes around the business centers of large cities with an inner belt highway, the population of the displaced area was a racial and ethnic mix. By the 1950s, white flight to suburbia was under way, and the areas of dense traffic flow and cheap land near downtown areas had become populated largely by African American families and businesses. Initially, this population had little effect on route selection of the new highways in the nation's cities, and African American

neighborhoods in Chicago, Miami, New York, and other cities were destroyed.

By the mid-1960s the civil rights movement had changed the political climate of the country. Civil rights struggles had given African American leaders the tools to fight the destruction of inner-city neighborhoods, and organized protests against road construction that was decried as another example of "institutionalized racism" became common. Activists in New York City; Baltimore; Washington, D.C.; New Orleans, and other cities organized to stop construction through neighborhoods. Sometimes the protestors lost. State engineers and local politicians succeeded in building elevated expressways through African American districts in Miami; Baltimore; Indianapolis; New Orleans; Nashville; Columbus, Ohio; and Montgomery, Alabama. But the protests started a change that gained in power as environmentalists added their voices.

The Highway Teardown Movement

By the 1970s, civic leaders in cities such as Portland, Oregon; and Milwaukee, Wisconsin, were heading coalitions of citizens who were pushing to tear down freeways and put cities back together or to provide access again to rivers and lakes blocked by multilane highways. The interstate system that had promised deliverance from urban blight in the beginning was increasingly viewed as a hindrance to urban redevelopment. During the 1980s, groups—many of them public-private partnerships—first conceived of expressway teardowns as opening areas for new forms of economic development, such as waterfront developments, expanded universities and medical centers, new downtown parks, and cultural attractions. During the 1990s, expressway teardowns continued to provide space for such developments. At the same time, environmental concerns moved the national transportation focus from roads to rails.

At the end of the first decade of the 21st century, the Interstate Highway System was plagued by deferred maintenance problems and collapsing bridges. Some cities and states responded by adding to the freeway system. Houston added a third outer beltway; Phoenix planned future highways to accommodate growth over the next four decades; and states, including Maine, Georgia, Alabama, Arkansas, and Nevada, proposed new interstate links. Teardown projects continued to gain impetus in New York City,

A wide swath of Interstate Highway 70 runs through downtown St. Louis, Missouri, as seen from the top of the Gateway Arch. Missouri and Kansas were the sites of the first completed sections of the Interstate Highway System.

New Orleans, and Nashville. Without equaling the politicized revolts of the 1960s, the era that has been termed *post-interstate* seems likely to continue to be a period of clashes between cars and cities and evolving efforts to revitalize the nation's cities.

In-Vehicle Computers

Automotive marketing research firm AutoPacific lists 65 features available in today's automobiles, that use computers—in addition to the microprocessors used in standard features. Even a new car in the lowest price tier with no extra features is equipped with about 30 computers, and at the other end of the spectrum, every function of a vehicle can be computer-assisted or monitored. In-vehicle computers are used in devices such as Global Positioning System data receivers, satellite radio, drowsiness alert systems, and Volvo's City Safety system, which prevents the car from tailgating.

In-vehicle computers were developed in the early years of the computer industry in the late 1960s and early 1970s, both by computer designers hoping to attract automobile manufacturers as customers and by in-house departments in automobile companies. General Motors, for instance, created the Electronic Control Systems Department in 1971.

Even before the introduction of the first major home computers in the early 1980s, 4-bit microprocessors were incorporated into car designs with cruise control, traction control, and antilock brake control. Other functions followed, made possible by in-vehicle computers: digital speedometers and trip mileage counters, speed warning systems, automatic door locks, and engine control features like ignition spark advance and dwell controls. By 1980, microprocessors were in use to improve emissions systems.

Today, in-vehicle computers are called electronic control units. While early microprocessors used compact, efficient algorithms because of the memory and processing constraints imposed by the technology of the time, systems in today's automobiles may use as many as 100 million lines of code. Some of these systems exist simply to protect against malfunction in other systems, for instance, safeguarding against the effects of electronic interference and preventing sudden braking or acceleration in the event of a system shorting out. This code is sometimes called "defensive programming."

One of the key electronic control units is the engine control unit (sometimes subsumed into a powertrain control module, which also includes a transmission control unit). The engine control unit is responsible for optimizing the performance of a car's internal combustion engine by adjusting the engine's actuators in response to conditions, replacing the older means of using mechanical and pneumatic systems to adjust air/fuel mixture, idle speed, and ignition timing. The idea of an engine control unit considerably predates the use of in-vehicle computers, but it was the use of microprocessors in automobiles that allowed the vision of early engineers to be effectively realized.

Though many manufacturers have proprietary systems in their vehicles, basic descriptive terms tend to describe a class of electronic control units. Airbag control units, for instance, govern the functioning of the airbag feature, while seat control units govern seat functions. Body control modules govern and monitor the electronic systems in the body of the car, from power window and power mirror systems to air conditioning to the immobilizer. The various systems of the car communicate with each other by means of the vehicle bus, which also includes the on-board diagnostics (OBD) connector, required in all American automobiles since 1996. *Bus* in this case is a computing term for a

system responsible for handling data transfers and other functions between systems either within a computer or among multiple computers.

The earliest forms of OBD systems were introduced in the 1980s as the use of electronic control units in cars became more common. When more and more systems are handled electronically and with microprocessors rather than with mechanical parts, the task of identifying the cause of a problem becomes more difficult and one that (barring the source being a broken connection or frayed wire) cannot often be identified through a visual inspection. Further, many of the systems include components that are tedious enough to access that it is not desirable to do so until the mechanic is sure it is necessary. OBD systems diagnose and communicate problems in order to let a mechanic know which component has failed. More recent and sophisticated OBD systems use an industry-standardized system of diagnostic trouble codes (DTCs) in order to identify the exact problem, although without the equipment to access the OBD system, a driver will be notified usually only through vague means like the “check engine” light. OBD is standardized not only in its use of codes but at the hardware level, with OBD-II using a standardized female 16-pin connector as its hardware interface. Other elements of the system are left to the manufacturer’s discretion in order to leave room for reporting information about unique or proprietary systems unique to a particular make or model.

Electronic control units include extensive monitoring systems in order to collect the information needed to let the unit know when and how to respond—by changing gears, for instance, in an automatic transmission, or by turning on a cooling fan to adjust temperature. The vehicle bus is a central network that was introduced as a solution to the growing problem of building physical connections between the various electronic control units that constituted the increasingly sophisticated computer systems of automobiles. Such wiring needed to be custom tailored to each possible configuration of features on each model, making aftermarket additions more complicated as well as often complicating repairs to the electronics. Improvements or new designs also required more extensive testing with this system. A central network, on the other hand, handles communications functions and

is easier to maintain or repair, while also making it much easier to add, remove, or modify features. Signals are transmitted along media ranging from single wires or fiber optics to more sophisticated paired wires in military vehicles where redundancy is even more important.

A wide variety of transmission protocols have been developed; they are the in-vehicle computer equivalent of the TCP/IP protocol used for transmissions on the Internet. BMW, for instance, developed Byteflight, a proprietary vehicle bus protocol that uses both synchronous and asynchronous communications using the time division multiple access (TDMA) standard. Byteflight is a descendent of FlexRay, a protocol developed and used by a consortium of members, including BMW, Volkswagen, Daimler, General Motors, and several semiconductor manufacturers. Though FlexRay disbanded in 2009, the protocol remains in use in, for instance, the BMW 5 Series Gran Turismo, the Audi A6, and the Rolls-Royce Ghost. Mercedes Benz uses D2B (domestic digital bus), which is designed for use with fiber-optic transmission media. Some of the protocols developed for use by automotive computers have since been repurposed for similar use in medical equipment, construction equipment, and automated systems in factories.

Jitneys

Jitneys have long operated in the space between sanctioned public transportation and the private automobile. Jitneys take many forms: vans, cars, shared taxis, minibuses, buses, and even motorcycles. They are operated in numerous ways: semi-fixed routes, fixed routes with variable stops, and complete passenger control over pickups and drop-offs. Initially, the 5-cent fare (known as a “jitney”) was the sole distinguishing feature of the services, but today they often work in cooperative fleets and are highly organized. A brief history of jitneys and two cases are presented here to provide an overview of issues associated with these services.

The precise dates and origins of jitney services are fuzzy. In the United States, the *New York Times* first mentioned the rapid proliferation of jitney services across the country in a January 31, 1915, article titled, “‘Jitney’ Bus Is Taking Many Cities by Storm.” Many accounts trace the origin of jitneys to southern and western cities in North America—most likely somewhere in California—in about 1914, and attribute its development to high levels of unemployment, the novelty of riding in a car, the availability of inexpensive secondhand cars, and advertisements in local newspapers.

Both historically and currently, labor issues with conventional transit have led to increases in jitney operations. For instance, a 1913 streetcar strike in

Phoenix created an opportunity for jitney operators to establish their burgeoning service without competition, and a 1982 transit workers strike in New York City spurred the creation of modern jitney fleets in the city. In the early years, municipalities in the United States and Canada worked hard to curb the creep of jitneys by implementing both reasonable and onerous regulations to protect existing streetcar monopolies and union-organized labor. While such reforms reduced the number of jitneys legally operating, the services remained popular with the public for a variety of reasons. In comparison to fixed-route transit systems, jitneys offered the allure of point-to-point flexibility as paved roads became ubiquitous and automobile transportation became predominant during the Interwar period.

Even though mass motorization dominated North American transport for the last 100 years, jitneys never fully receded into the annals of transportation lore. Unlike capital-intensive, rail-based transportation, jitneys merely require a comparatively inexpensive vehicle and a driver, keeping the barriers to entry for jitney operations relatively minimal.

Jitneys have found eager adopters within segments of urban society. The primary users are those unable to purchase cars or whom public transit serves poorly, namely new immigrants. Over the last 100 years, Americans’ travel habits have changed, but jitneys have retooled along with them. These services have become more organized and

formalized to keep up with the times and to appeal to a new base of consumers. The international adoption of jitneys matches the North American experience, where, once again, the services have grown up in response to high levels of unemployment, declining or nonexistent public transportation, the changing spatial structure of cities, an influx of automobiles, and vast networks of paved roads.

The international context varies considerably from city to city and country to country, but this entry will showcase commonalities by highlighting three key international examples from South Africa, Mexico, and Peru, and two cases from the United States, Chicago and New York. While the root causes of jitney growth differ in the international context—apartheid in Cape Town, insolvency in Lima, and fiscal constraints combined with prodigious road-building in Mexico City—the cases share one key characteristic: the public sector or a private-public transportation monopoly failed to meet the demand for transportation services. Across all cases, it is clear that jitneys emerged when sanctioned providers neglected or lacked the wherewithal to satisfy the public-transportation-riding public.

Development

Dissatisfaction with public transportation, growing cost burdens, shifting demographics, labor strife, and high levels of unemployment unify the international and North American jitney experience. The jitney emerged as a wedge mode of transport for those people in cities who were without access to automobiles or reliable transit. In addition, for those left out of the labor market—this is especially true in apartheid-era South Africa but also for recent Caribbean immigrants in New York and Miami—driving jitneys provided employment where few other options existed.

In the 1910s, the private automobile was still a novelty enjoyed by the elite, and cities were organized around public transportation networks—even though they may have been inadequate. The example of Chicago underscores the mismatch between the capacity of streetcars and the expanding needs of Chicagoans. This is the service mismatch thesis, where Chicago's public transportation riders demanded more "door-to-door" services, like the taxicab, and shorter headway times from streetcar operators. In the first half of this decade, Chicagoans without cars had few options other than

to patronize streetcars and elevated trains, even though public sentiment reflected a growing desire for the point-to-point flexibility of automobiles. A 1915 strike of elevated and surface streetcar operations, however, frayed public perceptions of public transportation and allowed Chicagoans to sample jitneys on a citywide scale with impunity. While the streetcars and elevated railcars survived the strike, riders had been exposed to the advantages of jitneys and taxicabs vis-à-vis their fixed-route competitors.

The experiences of Lima, Peru, share much in common with Chicago's. Much like North American cities, the local government granted concessions to private companies at the start of the 20th century. These concessions granted monopoly status to transportation providers on key routes, while *colectivos*, the Spanish term for jitneys, operated illegally. By the 1950s, many of these sanctioned private bus companies began to file for bankruptcy. The government intervened in 1965, but its plan to roll out of a fleet of 210 buses was inadequate to provide transport service to the rapidly expanding city. The city did not have the financial resources to bankroll an extensive bus network, but the 6,000 illegal *colectivos* were able to provide transportation connections for the vast majority of the public.

Despite the government's attempt to take over public transportation in the 1960s, it was unable to provide the flexibility of routes or frequencies necessary to meet demand. As in the case of Chicago, and really every city where jitneys thrive, the gap between supply and demand provided an obvious point of entry for jitneys in spite of legal obstacles. In sum, the *colectivos* were illegal, but the city depended on their service.

The development of Mexico City's *peseros* shares much in common with jitneys in Lima and Chicago, but this case also highlights the impact of land-use decisions and public investment in infrastructure on public transportation and alternatives. Like Lima, Mexico City underwent intense population growth during the 20th century. Electric trolley service first debuted in 1900 and buses came along 17 years later. The two modes operated side-by-side with both receiving subsidies. To cope with growing congestion, the government widened roads and constructed highways, which in turn opened up more land for development.

During this period of intense growth in automobile use, road building, and regional expansion, the

government also invested in public transportation. In 1969 and 1970, Mexico City introduced three new subway lines. While the government built public transportation infrastructure, it began cutting bus service to conserve money and break the labor union's control over contracts. It was during this period that licensed taxis and jitneys expanded their operations. By 1993, nearly 75,000 *peseros* accounted for more than 50 percent of all vehicle trips in Mexico City. The Mexico City subway remains widely used, but again, the shifting structure of the city favors the flexibility of the minibuses over the subway's fixed route.

The case of Cape Town aligns with many of the general trends identified in the previous examples. Jitneys first emerged in the 1920s, but they were

heavily regulated to protect the railroad monopoly and suppress the expanding black economy. The Group Areas Act of 1950 enforced racial segregation and the construction of black townships beyond Cape Town's Central Business District. While South Africa's economy boomed, the government subsidized the costs of racial segregation, but over time—with an economic crisis in the 1970s providing extra pressure—it became too burdensome for the government to maintain separate infrastructures for white and black areas and to build a road network to satisfy the growing number of drivers.

Because townships were purposely placed on the periphery of the city, public transportation was required to operate over long distances. This, too, eventually became too expensive, and by the 1970s

A taxi park filled with privately operated minibus-taxis in Kampala, Uganda, where they are called matatus. Jitneys frequently develop when sanctioned providers neglect or lack the wherewithal to satisfy those using public transportation. In the example of Cape Town, South Africa, jitneys in the form of minibus-taxis provide 29 percent of all public transportation trips within the city.

and 1980s, the government slashed subsidies for public transportation. The financial strain and spatial fragmentation created the perfect storm for widespread jitney adoption throughout South Africa. In the case of Cape Town, spatial fragmentation, macro-level economic circumstances, and black unemployment spurred the transition from subsidized public transportation to privately provisioned jitneys.

Regulatory Response in New York

Although the adoption of jitneys grew out of genuine transportation needs and, often, government failure, government response to regulating them has been inconsistent. In the North American context, the bulk of jitneys were regulated out of existence in the 1920s. Illegal jitneys continued to operate and reemerged as a vital transportation option in the 1970s and 1980s. The experience of *dollar vans* (a local term for jitneys) in New York is a good example of this phenomenon.

Beyond the United States, the response has also been inconsistent: Governments recognize the utility of jitneys, but their policies have generally been stacked against them. In South Africa, concerns about taxes, public health, and violence have all motivated the government to play a larger role in the industry. The recent rise of bus rapid transit (BRT) in South America, Asia, and Africa has in part been a strategy to clamp down on ad hoc jitney operations and replace them with a formalized BRT system. In South Africa, policymakers have used BRT as an opportunity to cleanse their cities of jitneys altogether. Despite universal governmental intervention, jitneys have proven to be resilient.

New York's story is much like the previous cases examined. Dissatisfaction with public transportation, economic contraction, a lengthy transit strike, and high unemployment contributed greatly to a jitney revival in the 1970s. The municipal government refused to regulate jitneys directly until 1993, when, with the passage of Local Law 115, a legal classification and regulatory regime was established for *commuter vans* (the legal term for jitneys in New York). Local Law 115 defines commuter van service as a "transportation service through the use of one or more commuter vans on a prearranged regular daily basis, over nonspecified or irregular routes."

This definition strips freewheeling jitneys of their flexibility and turns them into another predictable

transportation mode that can be monitored and observed centrally. While Local Law 115 severely limits commuter vans from providing transit-like service, the body tasked with regulating them, the Taxi & Limousine Commission (TLC) lacks the resources to enforce the law. Because the TLC cannot control commuter vans adequately, most flout the law. They do not prearrange rides, they accept street hails, and they pick up passengers at designated bus stops.

Dollar vans have remained vital in New York because they have managed to circumvent regulations and maintain much of the flexibility that made them so popular a century ago—namely semifixed routes and short headways. At the same time, the TLC requires all licensed vans to obtain insurance and submit to routine inspections, and these regulations, unlike the restrictions on street hails, have helped maintain a minimum standard of safety and service without sapping dollar vans of their appeal.

More recently, the dollar vans have demonstrated their value in crises. During transit strikes and extreme storms that have immobilized buses and subways, the dollar vans have come out en masse to pick up fares and transport passengers. During the 2005 transit strike that shutdown New York's public transportation system, dollar vans stepped in and provided service. The role of commuter vans during the 2005 strike highlighted their capacity to provide high-quality public transportation, exposed the failures of Local Law 115, and reinforced the idea that dollar vans contribute a valuable service to New York.

Regulatory Response in Cape Town

The regulatory reaction in Cape Town follows similar trends to the New York case. *Minibus-taxis* (a local term for jitneys) are vital to the city's functioning, but government officials are uncertain of how to make use of the fleet of minibus-taxis that ply Cape Town's streets. While there has been governmental intervention, the results are ambiguous.

Cape Town differs from New York in four important ways: (1) minibus-taxis are the overwhelming public transportation mode of choice throughout South Africa and make up 29 percent of public transportation trips in Cape Town; (2) because of the magnitude of the minibus-taxi phenomenon, regulations come from all levels of government, which creates confusion over precedent and enforcement;

(3) despite being classified as informal, operators and drivers are organized into associations, have their own unions to represent their interests, and organized “taxi ranks” throughout Cape Town serve as important destination points for minibus-taxis; and (4) in recent years, the national government has promoted Bus Rapid Transit as a way of eradicating minibus-taxis and formalizing the sector.

Cape Town differs from other cities in South Africa because it has a well-used commuter rail line. In 2004, there were 1.1 million public transport trips per day, of which 53 percent were served by rail, 29 percent by minibus-taxi, and 18 percent by privately operated but publicly subsidized buses. While Cape Town’s reliance on minibus-taxis pales in comparison to Johannesburg, Cape Town has between 7,500 and 12,500 legal and illegal minibus-taxis providing 332,407 daily rides. Since 1996, ridership has more than doubled from 150,000 rides per day. Government documents estimate that 70 percent of Cape Town’s 565 routes are oversupplied, which causes outbursts of violence among competitors, contributes to congestion, and discourages operators from maintaining their vehicles.

Transportation regulations come from all levels of government in South Africa. This creates overlap, uncertainty, and competing agendas among different agencies focused on different elements of the transportation system. Before 1977, the minibus-taxi industry was completely illegal. As the apartheid-era government began deregulating public transportation, it became increasingly clear that minibus-taxis would play a significant role in the future of South African public transportation.

The 1985 White Paper on National Transport established a quota system to regulate the number of minibus-taxis operating in different parts of the country. In 1987, the South African government sanctioned the use of 16-seat vehicles rather than nine-seat vehicles and further deregulated the industry. The quota system was eliminated, which allowed illegal operators to become legitimate. Since 1995, with the creation of the National Taxi Task Team, the national government has tried to enact policies to encourage greater formalization and control over the minibus-taxi industry.

In 2001, the National Department of Transportation created the South African National Taxi Council to improve negotiations between the numerous

and disparate minibus-taxi operators on policies related to subsidy and regulation. While this has improved dialogue, the industry clings to its outsider heritage and takes enormous pride in being controlled by black entrepreneurs.

In addition to national policies, the city of Cape Town has authority over municipal public transportation, municipal roads, traffic and parking, and municipal planning. While these powers seem straightforward, the overlap between different regulatory bodies and enforcement of existing policies makes it difficult for the city to enact comprehensive plans. In addition, minibus-taxis are privately operated. Thus, regulations determined by the national department of transportation and provincial and local governments also need to be approved by the taxi associations, which are made up of minibus-taxi operators.

A recent effort to convert minibus-taxi permit holders into operating licenses—as a way of weeding out inactive permit holders—has foundered because only 40 percent of permit holders have bothered to acknowledge the policy. The struggle to coordinate with minibus-taxis reduces the effectiveness of other policies, such as the ongoing taxi recapitalization intended to incentivize operators to upgrade their fleet or take a one-time cash payout of 50,000 rand, or about \$6,000, to exit the industry. Without a clear idea of how many minibus-taxis have active permits, it is difficult to allocate enough resources to make the program run smoothly.

Cape Town has been working for several years on its Integrated Transport Plan to consolidate control over the transportation planning functions of the city. The 2006 to 2011 phase of the plan addressed the confusion created by the different regulatory claims made by national, regional, and local entities and argues for the creation of a central transport authority in the city that determines transportation policies.

While different levels of government attempt to coordinate with the minibus-taxi industry, the industry has formed its own structure. The main components of the industry are taxi associations, unions (separate for operators and drivers), owner-drivers, fleet-owners, taxi drivers, queue marshals, minibus-taxi washers, money collectors, and mechanics. Since minibus-taxi operators and drivers have organized themselves and created a robust industry that comprises between 120,000 to

140,000 minibus taxis, they play a significant role in determining regulations. The taxi associations emerged to allocate routes, settle disputes, arrange insurance, secure financing for the purchase of new vehicles, and negotiate with the government.

The emergence of BRT in Cape Town has the explicit intention of optimizing the public transportation network and stripping away the clutter created by the minibus-taxis. While the Cape Town's MyCiTi Integrated Rapid Transit (IRT) system promises to absorb operators affected by the new system if they abandon their minibus-taxi operating licenses, minibus-taxi operators have been slow to give up prized routes and skeptical of governmental intervention. Without good data on ridership, operators' incomes, or the number of vehicles on the road, the government has little information to calibrate incentives adequately. With so much unknown about the minibus-taxi industry, MyCiTi has gotten off to a sluggish start and has been plagued by delays, labor disputes, low ridership, and cost overruns.

Conclusion

Jitneys are informal transit services found in nearly every large city in the world. The services are often overlooked by transport planners and scholars, but they fill gaps in service not covered by conventional transit. In some cases, these gaps are geographic—where jitneys operate no other transit does—and in some cases, the gaps are a result of income or social class. In all cases, jitneys have a long history of operating on the edges of conventional transit services. In many cities, jitneys are lifeline transit service for many, even in cities like New York with vast public transportation networks.

The relative success of jitneys comes from the ease of entry into the market and the demand from riders for more flexible services and routes than public transportation can provide. In many areas, the only barrier to entry is the possession of a vehicle. Yet, even though jitneys are resilient transit service, efforts to formalize jitney services have been difficult. In many North American cities, such attempts have led to degradation of the services. Cape Town provides an example of how jitneys might be used as a feeder within the broader transit system, but, again, there have been problems with implementation that are similar to other attempts to formalize informal transit.

Jitneys remain an important mode of transit for the public, but they are still poorly understood by researchers and policy makers. Minibuses offer great promise for improving the lives of people without access to other public transportation options. Jitneys also can extend the reach of conventional transit by acting as feeder systems. Unfortunately, because jitneys have operated somewhat outside the mainstream, it has been difficult to identify best practices from which policies can be drawn. As a result, jitneys remain a popular and important transportation option with much promise that has yet to be tapped.

Job Access and Reverse Commuting Program

Over the last half-century, employment has sprawled along with the influx of suburban office and industrial parks. The spatial mismatch hypothesis suggests that low-income households have remained in the metropolitan core despite the

suburbanization of employment, resulting in higher levels of unemployment and longer commute times for low-income households. Reverse commuting programs have attempted to break down the geographic barriers that have plagued low-income job seekers since the 1970s but typically suffered from inconsistent usage and a lack of long-term funding.

Low-income people rely heavily on public transit systems because they typically do not have sufficient resources to purchase and maintain cars, but traditional transit schedules and systems are unable to bridge the geographic gap between low-income people and employment opportunities. Public transportation has historically been geared toward moving commuters from the suburbs to the central city. This pattern means that public transportation routes are designed to accommodate greater inbound frequency in the morning hours and outbound frequency in the evening, schedules that operate in the wrong direction to adequately serve low-income people trying to access suburban employment. Low-income people are also hampered by commuter systems that do not meet the needs of workers with nonstandard hours or those who are trip-chaining, meaning that they must make several stops on the way to or from work to take children to school or pick up groceries, for example.

Program Goals

In order to meet the challenges of suburbanizing employment, the 1998 Transportation Equity Act for the 21st Century established the Job Access and Reverse Commuting (JARC) program. In 2005, the Safe, Accountable, Flexible, Efficient Transportation Equity Act: A Legacy for Users reauthorized JARC as a formula-based program. Designed to rectify the spatial barrier between low-income people and suburbanized employment, JARC has several goals.

First, the program aims to connect low-income residents of central city areas to employment centers in the suburbs. (Low-income people are defined as those who are at or below 150 percent of the federal poverty line.) A second goal is to build interagency collaborations, broadening the potential scope of funded projects. Although narrow transit experiments could possibly produce valuable lessons or solutions, the broader approach can address larger systematic transportation needs. The final goal is to use collaborations

as a mechanism for leveraging local funds and building diverse partnerships.

Funding

The leveraging of local funds is promoted through the program's funding structure. Eligible recipients include state and public entities. Funds are then passed to subrecipients, such as nonprofits, local governments, and public transportation operators. The Federal Transit Administration allocates 60 percent of JARC funds to large urban areas, 20 percent to small urban areas, and 20 percent to rural or smaller urban areas. Local recipients are expected to match federal contributions; the federal portion can be no more than 80 percent for eligible capital and planning costs and no more than 50 percent for operating costs. Ten percent of funds can be used for administrative costs with no required match for this activity.

The eligible uses for JARC funding correspond directly to the programmatic goals. Though subsidizing vehicle purchases for low-income individuals would provide access to employment, car ownership is not an eligible use of JARC funding because it would come at a high cost per person and would be an ineffective means for addressing large-scale transit problems. Eligible uses, therefore, encourage projects that involve mass transit.

Recipients can use JARC funds to extend service times, expand routes, and acquire mapping and dispatch technologies. JARC-funded programs include car loans for shared riders, as well as shuttle, rideshare, and carpool services. A portion of JARC funds can be used for administrative aspects of program implementation, including hiring and marketing. In addition to specifying appropriate uses of monetary allocations, the legislation requires that projects be based on locally developed plans that include both transportation and human services components.

JARC-funded projects have largely met the programmatic goals and consistently followed the guidelines for eligible uses. Many organizations have used JARC funds to develop comparable programs, suggesting that communities across geographies had similar areas of concern. For instance, several entities developed transit services that would allow parents to drop off children at daycare centers or school before work. Other recipients extended hours and routes for existing fixed-route

systems. Both approaches helped users search for jobs and provided access to job training programs, eventually leading to employment.

The implementation of carpooling, mapping, and dispatch software helped improve system efficiency for several communities. At the same time, the localized nature of JARC allowed organizations to develop programs that responded to less common community concerns. One JARC recipient, for example, created an emergency ride home program after users expressed a fear of being stranded at work when their children or families have unexpected needs.

Challenges and Benefits

Recipients generally feel that JARC-funded programs in their communities are successful but not without challenges. One of those challenges is caused by the dispersed geography of suburban employment; while public transit may be able to get employees to a designated suburban station, they may still be several miles from their actual place of work. Perhaps the greatest challenge, scholars have noted, is the complexity of systematic problems that have led to the spatial mismatch, and transit alone is not a sufficient solution to those larger social issues. While transportation can provide access to jobs, reductions in discrimination and segregation are necessary to fully address the entrenched social problems.

Nonetheless, JARC has produced significant benefits. The investment in reverse-commute transportation has the potential to reduce the number of welfare recipients by removing the spatial barrier to employment opportunities. In that way, public transit is a necessary component for reducing poverty and dependence on public assistance programs. Low-income people have cited lack of transportation as a significant barrier to finding and maintaining employment; JARC effectively removes that barrier.

The return on investment is substantial. For every dollar spent through the JARC program, the return is between \$1.50 and \$3.50. The benefits grow over time; over a user's work life, the return on every dollar spent exceeds \$15. The investment results in reduced future costs by increasing employment outcomes. In addition to the financial benefits, JARC allows for the development of new services and collaborations, ensuring

that low-income people have adequate access to opportunities.

Jobs–Housing Balance/ Spatial Mismatch

The concept of spatial mismatch usually refers to the geographical distance between jobs and residences. The phenomenon is a feature of most North American cities, but it can also be observed in other

dispersed or decentralized urban areas. Spatial mismatch is socially and politically relevant because it tends to affect disproportionately the employment prospects of individuals in low-income or ethnic minority communities. The problem is also important for transportation policy because job accessibility depends not only on distance to a job but also on the means of transportation available to the populations living in different parts of the city.

The hypothesis of spatial mismatch has been studied since the late 1960s, usually in the context of North American cities. A large body of evidence points to a high degree of spatial separation between jobs and residences of low-income individuals and ethnic minorities. This phenomenon arises due to a relative concentration of low-income and minority populations in central areas, while the jobs to which they are mostly qualified tend to be dispersed across the suburban landscape. The majority of the studies of this problem have focused on the case of black workers, although there is also significant evidence that other groups, such as the Hispanics, face similar problems.

The problem is relevant because it has been linked to high unemployment rates and low wages.

Distance and travel costs dissuade individuals living in central areas from actively searching for and taking jobs in difficult-to-access suburban areas, reducing their employment choices. Although there is evidence that the same type of job pays lower wages in central areas than in the suburbs, the high commuting costs and time necessary to access suburban jobs offsets the higher pay.

The emergence of the spatial mismatch phenomenon is explained by the population and land use dynamics affecting North American cities since the 1950s, which are characterized by urban sprawl, suburbanization, and dispersion of jobs. The expansion and improvement of the road network and the growth in car ownership rates enabled workers to commute from longer distances. Meanwhile, employers often migrated to suburban areas, too, leading to commuting patterns that varied from the traditional model of commuting from the suburbs to a central location. As these changes have occurred, white people became more concentrated in the suburbs and minorities in central areas.

Spatial mismatch becomes a greater problem when it is compounded by a high degree of spatial segregation of ethnic groups, which is common in

Abandoned public housing units in Buffalo, New York. In the United States, spatial mismatch tends to disproportionately affect the employment prospects of individuals in low-income or ethnic minority communities in urban centers, who may have limited access to suburban jobs. In some countries where residential mobility is controlled by government housing policies, spatial mismatch may instead affect workers living in suburban “new towns” who have limited access to jobs in the city center.

North American cities. Although overt discrimination in the housing market is not permitted by law, it does exist.

In addition, the higher costs of housing in suburbs prevents ethnic minorities and low-income people from moving. Households of the same ethnic groups are also concentrated in central urban areas for social and cultural reasons, because people often chose to live near friends and extended family. Evidence shows that minorities tend to have low degrees of residential mobility and are not as likely to move closer to jobs as whites.

Land use policies, such as zoning, may also have an indirect effect on racial and ethnic segregation, because they affect housing costs and the types of housing available in each neighborhood. The confluence of these factors leads to the stability of spatial segregation across time.

Transportation Availability

The problem of spatial mismatch between residences and jobs relates not only to geographic proximity, but also to the means of transportation available for the population in each neighborhood. For example, studies in many cities show that whites tend to commute longer distances, but blacks spend more time commuting. Realizing that transportation options play a role in job accessibility, some researchers have shifted their focus from the concept of spatial mismatch to that of modal mismatch. That is, they analyze the separation between jobs and residences in terms of access to suitable transportation.

Under this perspective, individuals are at a disadvantage if they do not have access to private transport or if the available public transportation options do not allow them to access areas with high concentrations of jobs at suitable times of the day. The provision of public transportation is, therefore, an important issue for policy-makers to address within the problem of spatial mismatch.

Spatial mismatch is increasingly a characteristic of many cities outside North America, which have gone through a steady process of decentralization and suburbanization, as well. In European cities, new employment centers are often located in suburban areas, near motorway junctions. At the same time, the historical city centers tend to lose population and to be increasingly inhabited by elderly people and racial minorities. However, the

mechanisms of spatial mismatch vary from country to country. In some countries, for example, access to transportation is less of a hindrance for workers than access to residential mobility, which is controlled by government housing policies. A different version of the problem of spatial mismatch has been identified in such cities as Singapore, where workers living in "new towns" in suburban areas have limited accessibility to jobs in the city center.

Just-in-Time Systems

The primary objective of contemporary capitalism is to increase profits. Thus, over time, manufacturers have developed a variety of techniques to maximize profits. One such technique is the use of just-in-time inventory systems. Through these systems, the ordering of components needed in the manufacturing process is delayed until the last possible moment. By delaying ordering, manufacturers are able to minimize warehouse costs and maximize overall profits.

Early experiments with just-in-time systems date back to the early 1900s, but the concept simply did not take off during that era. The just-in-time

systems utilized by contemporary corporations can be traced back to 1970s Japanese auto manufacturing. The 1973 oil crisis impacted Japan and many other countries negatively and contributed significantly to worldwide recession. Financial hardship forced companies to innovate or perish.

One of the innovators, Toyota, developed just-in-time systems in its automobile manufacturing. When Toyota's use of just-in-time systems enabled the company to outperform their similarly sized competitors, the competitors took notice. Just-in-time systems soon became an industry standard in Asia, and quickly became known in the rest of the world.

Despite the popularity of just-in-time systems with manufacturers, they are not without problems. One of the most hazardous issues is inherent in just-in-time systems: the precision of the last-minute timing of ordering makes manufacturers particularly vulnerable to downstream product shortages. Additionally, such shortages could be, intentionally or unintentionally, exacerbated by conflicts between labor and management. Furthermore, cultural disconnects between the American and Japanese corporate cultures have made it difficult for American facilities to adapt to just-in-time systems developed in Japan. Finally, critics have argued that the presumption of stability inherent in just-in-time systems may be inherently flawed.

How it Works

The aim of just-in-time systems is to remedy perceived inefficiencies in warehouse processes associated with traditional manufacturing. Prior to the development of just-in-time systems, manufacturers were dependent on warehouses during the production process because stockpiles of raw materials and/or components were used to ensure the flow of production. Manufacturers ordered parts at regular intervals to replenish these critical stockpiles. While this practice assured that parts would be available when needed, they required warehouse space and all the associated costs that go with warehousing.

When utilizing just-in-time systems, manufacturers only order parts when existing inventories reach a low point, thus minimizing storage costs. This process relies on signals between different points in the manufacturing process to alert inventory clerks when to order needed parts; thus the

term *just-in-time*. A variety of methods can be used to signal that components need to be ordered, ranging from highly technical inventory systems to simple visual checks.

Proponents of just-in-time systems argue that diminishing storage costs are just the beginning of the savings. Other potential benefits of just-in-time systems include optimizing the flow of production, involving employees in the manufacturing process and associated decision making, and improving the quality of the end product, which will likely increase sales and enhance the reputation of the product.

Just-in-time systems are dependent on a second process called lean production. Without lean production, just-in-time systems may actually harm profitability by slowing production and inhibiting profit through supply shortages. Lean production, at its root, is based on preserving the market value of the product while minimizing excess or inefficient work. All activity must be directed toward definite objectives that add to the value of the end product.

The development of lean production, again, was based on methods developed by Toyota, which identified "seven wastes": inefficient transportation, unneeded inventory, unneeded motion, waiting when value-adding production could be occurring, overprocessing the product, overproduction that creates unneeded surplus, and product defects. By combining just-in-time systems with lean production, Toyota became a manufacturing force. In fact, this combination has since become known industrywide as the Toyota Production System.

Despite the popularity of just-in-time systems and lean production in corporate America, a number of problematic issues have been identified, relating to both human responses to the systems and actual flaws in the assumptions behind just-in-time. At the most basic level, the disconnect between American and Japanese manufacturing culture, which was embedded early in the development of just-in-time systems, led to delays in the implementation of just-in-time systems in the United States.

Another pressing issue is that these types of systems leave consumers and downstream producers open to product shortages in the event of ordering failures at any point in the system. A related, but

equally serious, flaw is that the precision timing necessary for the systems to provide financial savings also makes them vulnerable in the case of labor issues, such as a strike, or industrial sabotage. Well-informed but discontented workers could potentially wreak havoc on the entire production system with only a few well-placed delays in ordering.

In addition to cultural and labor issues, research critical of just-in-time systems and lean production indicates that the reasoning behind the systems themselves may be flawed. In particular, it appears that basing just-in-time systems on the presumption of stability may be faulty.

Latent Travel Demand

Latent travel demand is the increase in travel demand that could be solely attributed to an increase in the transportation system's capacity. An expansion of the existing transportation network, such as the addition of a highway lane, may generate new trips that did not take place in the original system. These new trips represent the latent travel demand.

Rationale

Travel is a derived demand, that is, the demand for travel is an outcome of an individual's demand for some activity, such as work or recreation. Because activities are distributed in geographic space, individuals must travel between various locations to physically access those activities. Individuals make travel choices based on their preferences, available resources, and relative costs. Preferences include attitudes and tastes, for example, bicycling versus walking versus driving.

Travel cost has two components, time and money. Monetary cost is straightforward; it would include a public transit fare or the money spent to own and operate a private automobile. Time cost is not as straightforward because different individuals may value their time differently. Nonetheless, in relative terms, the less time travel takes, the lower the time cost.

To a large extent, the decision to make a trip depends on the cost of making the trip and the benefit or utility the individual would derive as a result of making the trip. For example, an individual may value the trip to work more than the trip to a hair salon. The corresponding cost an individual is willing to bear for making the work trip, then, is likely to be greater than the trip to a hair salon. It is not surprising, therefore, that work trips are usually the biggest part of any individual's travel budget, which comprises both time and money. It follows that the quantity of travel demanded will depend on the cost of travel, all else being equal. For example, an individual may not be willing to travel longer than a certain distance or spend more than a certain amount of money for a work trip, depending on the person's wage rate.

Expansion of transportation network capacity, for example, through the construction of a new highway link, is likely to improve traffic flows, thereby reducing travel times in the short term, especially in a previously congested network. If the monetary cost of travel, such as fuel prices, remains unchanged, then the new highway link would induce new trips solely because of the lower total travel cost, which, in this example, is the reduced travel time. These new trips are said to be the result of latent travel demand because they would not have taken place if the travel costs (in time) were any higher. It follows that in a congested

transportation network, any supply side intervention that reduces traffic congestion will generate additional trips because of latent travel demand, all else being equal.

Measurement

Researchers have often expressed latent travel demand as the elasticity of travel demand with respect to travel cost. An often-used measure for travel demand is the total number of vehicle miles traveled (VMT). VMT is, however, an imperfect measure. For example, trips rerouted over a shorter route, made possible because of a new highway link, reduces the number of miles traveled for all vehicles using the new route.

Travel cost is even more difficult to measure directly. For example, quantifying the time cost of travel is difficult because different individuals value time differently. An often-used proxy for travel cost is the total lane-miles of roadway in any given transportation network, which is frequently used in studies of the effect of transportation network expansion on travel demand.

Lane-miles, again, is an imperfect measure. Although travel time savings is a more appropriate measure, it is very difficult to accurately calculate. In contrast, measuring lane-miles is quite straightforward and can be done with accuracy fairly easily. Finally, an accurate assessment of latent travel demand, or more specifically, induced traffic, is extremely difficult due to the phenomenon of triple convergence. Nonetheless, the available empirical evidence supports existence of positive elasticity of travel demand with respect to network supply, thereby establishing existence of latent travel demand.

Policy Implications

Latent travel demand undermines supply-side interventions in reducing traffic congestion in the long term because additional trips generated as a result of latent travel demand neutralize the benefits of network expansion to a large extent. In theory, these new trips would not have taken place had the expansion not occurred. Hence, supply side interventions by themselves are not considered to be effective long-term remedies for addressing traffic congestion. Rather, transport network expansions should be accompanied by appropriate road pricing strategies to prevent generation of induced

traffic, thereby mitigating traffic congestion effectively in the long term.

Lead Pollution

A naturally occurring element, lead has been used for more than a century in industrial applications as an ingredient in fuel, paint, pipes and plumbing material, solders, ceramics, folk medicines, and even cosmetics. When manipulated and manufactured, the concentrations of lead in the air and soil can rise to levels unsafe for humans, animals, and the environment. However, because of the auspicious properties of lead—its malleability, nonconductivity, and resistance to corrosion—the substance was used with great frequency until the adverse health effects could no longer be ignored.

Despite widespread evidence of the harm of lead exposure, the manufacturers of some products continue to use lead, and some countries have yet to issue strong regulations against it. Current demand exceeds 10 million tons each year, primarily for leaded batteries and applications such as aviation fuel.

One of the largest contributors to lead pollution, and of particular interest in the context of this volume, was leaded gas manufactured for automobiles. Although the U.S. Environmental Protection Agency (EPA) began limiting the amount of lead that could be used in gasoline in the mid-1970s, it

was not fully phased out until January 1996, when the EPA banned the sale of leaded gas for on-road vehicle use. However, leaded gasoline remained legal for sale when used in off-road vehicles, including airplanes, farm equipment, race cars, and marine engines.

A number of U.S. statutes provide enforcement and regulatory authority to agencies, including the EPA and the U.S. Centers for Disease Control and Prevention (CDC), to regulate, track, and educate the public about the dangers of lead and lead exposure. Such laws include the Toxic Substances Control Act; the Residential Lead-Based Paint Hazard Reduction Act of 1992; the Clean Air Act; the Clean Water Act; the Safe Drinking Water Act; the Resource Conservation and Recovery Act; the Comprehensive Environmental Response, Compensation, and Liability Act; and the Lead Contamination Control Act of 1988.

Most of the world is on track to eliminate the use of leaded gas. In 1999, the World Bank promoted a global phase out of leaded gasoline. By 2011, the National Resources Defense Council announced that over 175 countries had removed lead from gasoline, with only countries such as North Korea, Afghanistan, Algeria, Iraq, Burma, and Yemen failing to ban leaded gas.

History

Leaded gasoline, which *Time* Magazine proclaimed one of the 50 worst inventions ever in 2010, solved a problem that was vexing Charles R. Kettering, the inventor of the self-starting engine. The 1912 Cadillac, produced by General Motors (GM), boasted Kettering's electric ignition, which eliminated the need to hand crank cars. However, drivers of the luxury car were distressed by an engine knocking sound that some attributed to the new starter technology.

Kettering realized the knocking was caused by the fuel, not his device, and he and his colleagues at the GM research laboratories in Dayton, Ohio, experimented with numerous additives to increase the octane level of the fuel and remove the engine knock. In the early 1920s, Thomas Midgley tested tetraethyl lead (TEL) and discovered that small amounts of TEL could do the trick for the power-hungry automobiles in GM's line. Midgley termed the fuel *ethyl gas*, and it became the dominant fuel for the next 50 years.

Both Kettering and Midgely had previously experimented with alcohol and ethanol gasoline blends, both of which had been used in earlier car models. These additives, renewable and nonpolluting, had a fatal flaw in the eyes of GM's decision makers: they were not profitable. GM preferred using TEL, which they also could patent.

Additionally, the CEO of General Motors, Pierre S. DuPont, and his brother Irénée DuPont, CEO of DuPont Company, were able to work together to profit from their exclusive rights to ethyl gasoline, which was advertised with the tagline "ethyl is to gasoline what vitamins are to food."

Ethyl gasoline for the East Coast was initially produced at a Standard Oil refinery in Bayway, New Jersey. Soon, workers at the plant called it the "loony gas building" because of the symptoms displayed by employees who worked closely with TEL, including memory loss, poor coordination, and sudden bursts of fury. Within a single week in 1924, five plant workers died and the majority of the men working with TEL were hospitalized. All told, over 80 percent of plant personnel died or suffered severe lead poisoning. New York City, Philadelphia, and other municipalities banned the sale of leaded gas after the New York City Medical Examiner's Office issued a damning report in the wake of the Bayway deaths.

To avert a national ban, GM and its partners halted sales of ethyl gas and initiated safety studies through the U.S. Bureau of Mines. Financed by the companies, the reports were farcical, with the final authority governing content and release resting with the companies themselves. Although some scientists who were approached by GM to test the ethyl gasoline refused to do so, the chief medical consultant for the gasoline, University of Cincinnati's Dr. Robert Kehoe, proclaimed no health risks were related to the leaded gasoline.

Ultimately, the industry, along with government support, was able to convince the public that leaded gas should remain unregulated. They successfully argued the position that they did not have to prove that ethyl was safe; instead, it was incumbent upon detractors to prove that the ethyl gas possessed dangerous qualities. They maintained that the worker illnesses and deaths were anomalies rather than the inherent result of close contact with TEL. The U.S. government overturned the local bans on leaded gasoline in 1926 and

injunctions were later issued to competitors who questioned the safety of the fuel.

Lead Exposure

In spite of the success of a few large companies in preventing regulation of leaded fuel in the 1920s, lead had been identified as dangerous as early as the Roman Empire. Commentators noted that lead, used by Romans to sweeten wine, deleteriously affected those who inhaled its fumes. In 1700, Italian physician Bernardo Ramazzini remarked that miners who worked with lead experienced what we would now label hallucinations or psychotic episodes. Benjamin Franklin and Charles Dickens both cautioned the public against the dangers of lead exposure. In the early years of the 20th century, physician Alice Hamilton studied lead poisoning among Illinois laborers and advocated for greater worker protection.

Over the ensuing century, lead has been identified as a toxic substance. Government agencies, including the National Institutes of Health (NIH), state that no amount of lead exposure is safe. For children, who are more susceptible to the ill effects of lead exposure and lead poisoning, the CDC advise that any child with a blood level of lead of more than 5 micrograms per deciliter should be considered at risk and that public health actions should be initiated.

Adults suffering lead poisoning experience decreased kidney function, disruptions of the reproductive system, decreased nervous system performance, cardiovascular distress, mental impairment, miscarriages, abnormal fetal development or premature birth in pregnant women, and death. The health effects of lead on children include decreased IQ, decreased academic achievement,

U.S. Environmental Protection Agency staff members collect water sampling devices surrounded by floating booms in the Lower Duwamish Waterway Superfund Site in Seattle, Washington, January 15, 2013. This waterway is seriously contaminated with chemicals from industry as well as from runoff from nearby streets and roads. As many as 1,272 of the 1,684 sites on the EPA's National Priority List of Superfund sites are contaminated with lead.

increased incidence of attention-related behaviors and behavior problems, reduced postnatal growth, delayed puberty, and hearing loss.

Researchers conducting a 300-person longitudinal study in Cincinnati, Ohio, found that exposure to high levels of lead in childhood impaired the development of the myelin sheath in the nervous system and destroyed prefrontal gray matter in the brain's cortex.

Some researchers, beginning in 2000 with Rick Nevin, an economist with the U.S. Department of Housing and Urban Development, have proposed that lower crime rates recorded in the United States since the 1990s were a result of the ban on leaded gas that started in the 1970s. Nevin and other scientists have investigated the correlation between crime statistics and bans on leaded gasoline and have seen similar results in various national, state, city, and international contexts. Research commissioned by the United Nations Environment Programme found that 58 million fewer crimes and 1.2 million fewer premature deaths have occurred because of the elimination of leaded gasoline.

Moving forward, the task remains to reduce the use of lead in other industries. Lead does not break down naturally. It can travel many miles by air and attach to soil particles. In some cases, lead travels to and contaminates groundwater. Lead had been found at 1,272 of the 1,684 sites on the National Priority List of Superfund sites identified by the EPA.

Levels of Service

Levels of service (LOS) is a set of performance or service-quality categories used in transportation planning. A system with six levels, ranked from A to F, was first published in 1965 in the *Highway Capacity Manual* published by the Transportation Research Board in the United States. The LOS concept has become a de facto standard in many other transportation contexts and is used for planning, to evaluate present road and traffic conditions, and to estimate the results of proposed changes such as widening roads.

LOS is a valuable tool for planning, particularly in the context for which it was originally developed—that of freeways—but applying the LOS concept in other contexts, such as urban areas, has been criticized as inappropriate.

Automobile Travel

In the six-letter LOS scale, each letter represents a range of conditions, representing the traveler's point of view. Level A represents the best operating conditions, with the lowest density of automobiles and high travel speeds, and Level F the worst, with highest density and slowest travel. Determining a level of service requires complex calculations regarding information such as service density

(defined as passenger cars per mile per lane), traffic speed, and flow, and the alphabetic system is meant to be a simple way to convey this information to the public. (Details about calculations are available in the *Highway Capacity Manual*.)

For freeways, Level A describes traffic that flows freely, at a high speed, and with density low enough that one car is not affected by another; for instance, it is easy for a driver to change lanes. At Level B, traffic flows freely and at a high speed, but drivers must be more aware of the presence of other cars when maneuvering. At Level C, drivers are highly influenced by the presence of other automobiles, so lane changes can be difficult, and a lane blockage can lead to a significant delay. At Level D, the flow of traffic is sufficient to force decreased travel speeds, maneuvering in traffic becomes difficult, and even a minor lane blockage can cause a significant delay. At Level E, operation is at or near capacity, and maneuvering is difficult. At Level F, traffic demand exceeds capacity, and cars are subject to stop-and-go driving or gridlock.

Other Applications

The LOS concept has also been applied in other areas, including bicycle travel, pedestrian travel, and parking facilities. Later editions of the *Highway Capacity Manual* included LOS standards for cyclists, pedestrians, and transit systems, but these have been criticized as being modeled on automobile standards and, therefore, as being overly concerned with traffic flow.

In 1998, Linda Dixon developed standards for pedestrian and bicycle levels of service, using a checklist that assigned points to different aspects of the walking or cycling environment, which were then added up and the total score was used to determine the LOS. For instance, for pedestrians, if a continuous sidewalk was available on both sides of the street, the area received a score of 6; if a continuous sidewalk was on only one side, a score of 4; and if the sidewalk was nonexistent or not continuous, a score of 0. Presence of shade trees was worth 0.5 point, while the presence of medians received one point, and so on. A total score greater than 17 received a LOS of A, 14.5 to 17 points, B, and the scale continued down to 3 or fewer points, which received a LOS of F. For bicycling, Dixon's checklist included factors such as lane width, unrestricted sight distance, and the maintenance condition of

the roadway. The same A-to-F scale was applied to the total score.

In 1996, Mary Smith described LOS for parking structures. Rather than a one-size-fits all scale, Smith suggests applying different criteria depending on characteristics of various users of the facility and the likely priorities of different user groups. For visitors who are unfamiliar with the facility, she suggests valuing Level A service based on factors related to the freedom to maneuver (for example, ramp slopes and turning radii) and flow capacity but placing lower priority on travel time within the facility. In contrast, she suggests that drivers who use a parking facility on a regular basis are more likely to be concerned with travel distance and wait time at entry and exit points. Such users would prefer Level A service in those categories but would be less concerned with factors related to freedom to maneuver, where they might accept Level D service.

Criticisms

LOS was developed during a period of expanding freeway construction, and the metric is based on the principle that freely flowing traffic is good and congestion is bad. It is not mandated for use in other applications but is often accepted as a de facto standard for all types of streets and multiple modes of transport.

In 2012, Gary Toth criticized the automatic application of LOS standards to urban areas, where movement patterns are not necessarily optimized for free traffic flow. In such areas, the standard is usually to have sufficient capacity to meet a C- or D-level LOS. He makes two related points: one is that free-flowing automobile traffic may not be a logical goal for an urban area; the other is that achieving easy traffic flow may require too high a price in terms of safety, quality of life, and other factors in the area.

He points out that the purpose of an urban street is not merely to move traffic—although that is clearly the main purpose of an interstate highway—but, rather, that the street forms part of people's living and working space. In the urban context, he argues, congestion is not necessarily a bad thing, and projects such as street widening, which would limit space for crosswalks and pedestrian access, make an urban area less desirable for the people who live there.

Another, more general, criticism of LOS is that it is applied as a single national standard, without accounting for local differences in how people view

traffic issues. This includes not only rural-urban differences in how streets are used, as cited by Toth, but also regional differences and preferences. Perhaps people in North Carolina are more willing to accept slower traffic flow than people in Maryland, for instance, or Chicagoans would accept a wait time at a traffic light that would be rejected as unreasonable in Atlanta.

Light Electric Vehicles

A light electric vehicle (LEV) is a land vehicle propelled by an electric motor that uses an energy storage device, such as a battery or fuel cell; has two or three wheels; and typically weighs less than 220.5

pounds (100 kilograms). LEVs range from the Segway personal transporter to power-assisted wheelchairs, one-person cars, personal rapid transit, and pedicabs (rickshaws), but the most common LEVs in the United States are electric bicycles and scooters.

LEVs are clean, efficient vehicles that save time and money and earn praise for their environmental friendliness. Despite these advantages, they remain a niche product in the United States. Some advocates insist the market will change in the future, an argument that gained weight in spring 2013 when Toyota introduced the i-Road Concept at an automobile show, promising 70 models in 2014.

The Segway

On December 3, 2001, the Segway Human Transporter was introduced amid much fanfare on ABC's morning news program *Good Morning America*. The Segway's creator, Dean Kamen, predicted that the LEV would change the world, quickly navigating city streets, easing congestion, and lowering pollutants. One investor publicly predicted sales of \$1 billion, and high-profile investors such as Amazon.com chief Jeff Bezos and Apple's Steve Jobs lent credence to the claim.

But, by 2010, only about 80,000 Segways were in use worldwide, and *Time* magazine named it one of the 50 worst inventions ever. Later the same year, the death of company owner Jimi Heselden, after falling from a cliff while riding his Segway on his British estate, garnered headlines around the world. Ironically, the tycoon's company had only acquired Segway in December 2009. In December 2010, a student who suffered a traumatic brain injury when he fell during a Segway competition won a \$10-million verdict against the company. Segway was bought by Tennessee-based Summit Strategic Investments in 2013. Summit promised expansion and the release of new products.

Electric Scooters and Bicycles

Once a toy for children, electric scooters have been adopted by adults as an economical and emissions-free method of personal transportation. Some are designed primarily for campus travel; others are used on city streets. Between 2007 and 2008, the number of scooters on city streets in the United States increased 200 percent. As of 2012, there were more than 1 million of them in the United States. A wide selection of electric scooters

A two-wheeled C-1 electric vehicle built by Lit Motors. The C-1, which is expected to sell for \$24,000, can reach speeds of up to 120 mph and travel 200 miles on a single charge.

is available, with speeds starting below 10 miles per hour (mph) and reaching up to 30 mph; they can travel distances ranging from 15 to more than 60 miles, and prices start at less than \$1,000 and top off at around \$9,000.

Electric bicycles are not mopeds or motorcycles. They are bicycles that can either be pedaled in the traditional fashion or with an assist from the electric motor. Commuters in China and Europe use them, contributing to global sales of an estimated 29.3 million e-bikes in 2012 alone, as compared to about 120,000 electric cars sold worldwide. The price makes them attractive. Although a consumer can pay from \$29,000 to \$95,000 for an electric car, an e-bike starts at around \$500 for a basic model, about the same price as a top-of-the-line conventional bicycle. There is a German e-bike on the market, the Blacktrail BT-1, that claims a top speed of 65 mph and retails for \$80,000, but the average, good-quality e-bicycle sells for \$2,500 to \$3,000.

Price differences are moot, however, if no one in the United States is buying. Yet, with U.S. sales estimated at 159,000 units in 2012, the market does appear to be growing. Industry executives point out the increase in the number of Americans biking to work as a harbinger.

According to the League of American Bicyclists, bike commuting grew by 47 percent nationally between 2000 and 2011, and it grew by 80 percent

in communities designated as “bicycle friendly” by the league. Cities from coast to coast and points in between are becoming more bicycle friendly, with New York, Chicago, Washington, D.C., and Los Angeles building dedicated bike lanes.

The industry is targeting two groups: baby boomers concerned about exercise and weight, who are already returning to the bicycle in significant numbers, and urban buyers in their 20s and 30s, with less money to spend than older generations and not as much enchantment with the automobile. For both groups, the selling point for e-bicycles is that they reduce greenhouse gas emissions, air pollution, and traffic congestion.

The LEV of the Future

Despite the dreams of environmentalists and technologists, consumers have failed to embrace light electric vehicles in significant numbers in the United States. Dan Sperling, a professor of civil engineering and environmental science and policy at the University of California, Davis, and director of its Institute of Transportation Studies, sees the high cost of batteries for LEVs as the sticking point. While the technology in computer chips and digital storage has improved as they dropped in price, batteries have remained bulky and expensive.

Small startups and global companies alike are working to deliver affordable and practical vehicles to the mass market. Lit Motors, a company with a staff of 10, plans to introduce in 2014 the C-1, a cross between an electric motorcycle and a car with a top speed of 120 mph and the ability to travel 200 miles on a full charge. The vehicle, which will sell for \$24,000 for the first production run of 1,000, targets motorcyclists between 45 and 60 years old who are concerned about safety but don't want to give up their two-wheeler, and younger commuters who live in urban or suburban areas where driving a car may be less attractive. According to the *New York Times*, as of October 2012, about 250 people had already preordered the vehicle.

Toyota's i-Road Concept, introduced at the 2013 Geneva Motor Show, is powered by a lithium-ion battery paired to two 2-kilowatt (2.7-horsepower) electric motors driving the front wheels. According to Toyota, charging the i-Road should take about three hours using an ordinary 120-volt household power outlet. At 660 pounds, the i-Road is considerably heavier than electric bicycles and motorcycles,

and its top speed is only 28 mph, but Toyota is counting on it making up for what it lacks in speed in efficiency and environmental friendliness.

Light Pollution

Light pollution, which is excessive and misdirected artificial light, has become a serious threat to human health and the environment. It causes damaging effects on people and their habitat and also wastes billions of dollars and vast amounts of energy from unnecessary lighting.

Transportation both contributes to and is impacted by light pollution. Headlights, street lights, aviation lights, railway lights, and lighted signs for roadways and railway stations are just a few examples of how transportation systems feed artificial light into the environment. Although the environmental effects of transportation are supposed to be considered in all cases, civil engineers for many years have overlooked the impact of light pollution.

Environmental Problems

Human beings naturally derive their sleeping and waking schedules based on the rising and setting of the sun. For wildlife, too, natural rhythms and activities are tied to sunlight and darkness. Excessive light at night interferes with many necessary

activities for wildlife. Nocturnal creatures, in particular, are at risk because they no longer have the cover of darkness to protect them from predators or the natural signal that it is night and time to become active.

At the same time, much of the artificial light is not used for any purpose. Roughly one-third of all light pollution is wasted energy, which uses up 30 million barrels of oil and 8.2 million tons of coal each year at a cost in the United States about \$2 billion, according to the International Dark-Sky Association. In addition, the oil used emits nearly 14.1 million tons of carbon dioxide (CO₂) into the environment, which contributes to global warming.

Light Trespass

Light trespass is a form of light pollution that occurs when artificial light interferes with a person's normal dark cycle. Bright days and dark nights are essential for proper sleep cycles. For instance, streetlights or car headlights that spill over into one's backyard is considered light trespass. To combat light trespass, it is ideal to have artificial street lighting specifically directed at the roads, not at the surrounding residences.

Glare is a form of light pollution that directly impacts a person's eyes. This is regarded as the most dangerous side effect of light pollution. There are three different types of glare: blinding glare, which is so severe that the eyes cannot adjust to the darkness for some time even after the light source is removed; disability glare, which reduces visual performance; and discomfort glare, which, although it may not interfere with person's performance, creates annoyance and distraction. Discomfort glare is common for drivers on roads where they are not protected from the headlights beaming from cars traveling in the opposite direction at night.

Another form of excessive artificial light is referred to as clutter. When too many lights are placed in one location, the result is not better visual acuity but cluttered light, which is highly distracting, especially for drivers. Human eyes naturally adjust to low lighting and generally adapt well to dark areas. However, overly bright and abundant light prevents eyes from naturally adapting, so that dark areas adjacent to brightly lit areas are nearly impossible to see. Driving along unevenly lit roads at night, therefore, is especially dangerous.

This view of the city of Paris, France, in February 2008, shows how artificial light emanating from a city can scatter into the atmosphere and brighten the natural sky, an effect called urban sky glow. Almost 50 percent of urban sky glow is caused by street lighting. Approximately one-third of all light pollution is wasted energy, which costs about \$2 billion per year in the United States, and consumes as much as 30 million barrels of oil and 8.2 million tons of coal annually.

High-Mast Lighting and Urban Sky Glow

High-mast lighting is a series of tall poles, often greater than 60 feet tall, which point extreme lights toward the ground. These can be found often along highways to aid drivers at night, at stadiums and arenas that hold nighttime entertainment, or parking lots. While some have a circular shield to reduce light pollution, these devices generate great amounts of light, comparable to floodlights, and light pollution is inescapable.

When designing and building a new highway system, the pros and cons of high-mast lights must be considered before they are specified.

Urban sky glow involves all the various forms of artificial light coming from a city scattering into the atmosphere and brightening the natural sky. Street lighting causes nearly 50 percent of urban sky glow. Ninety-five percent of street lighting points toward

the ground, but it is then reflected off various surfaces and dispersed around the environment. Airplanes also cause significant light pollution and contribute to urban sky glow.

Light Pollution Planning and Policy

Of the many environmental impacts of transportation infrastructure, light pollution is widely ignored. Yet, it is the responsibility of traffic and civil engineers to properly manage projects early in the planning stages to identify and find solutions to problems that could be caused by lighting.

Researchers estimate that upward of 50 percent of all light pollution may result from roadway lighting. Overuse of artificial light not only damages the environment, but also affects wildlife, human circadian rhythms and the aesthetics of the outdoors. Mounting concern about outdoor lighting

has prompted bylaws in both the United States and Canada regarding the design of the lights.

Roadway lighting provides many benefits, of course. It serves as a supplement to headlights to help reduce nighttime accidents, deters crime, facilitates traffic flow, promotes businesses, inspires community growth, and insures safety for pedestrians. The benefits are a result of proper planning, however. If a lighting fixture is of poor quality or design, the light will not fall on the road but onto lawns or into homes. To prevent this light trespass, designers must create fixtures that use luminaires with light distributions that are suitable for the roadway for which they are intended. Calculations must be precise to determine the correct placement of each fixture.

Roadway planners should use energy efficient LED lights rather than halogen lights, which face upward. For the cost, these lights are more efficient for taxpayers and deliver the same safety effect for travelers. LED lights, however, still produce tinted blue lights, which can interfere with human night vision.

Therefore, roadway lighting systems should use energy-efficient, full-cutoff luminaires to control the amount of light emitted. The term *full-cutoff luminaire* refers to one that allows no direct light emission above a horizontal plane through the luminaire's lowest light-emitting part. Designers and planners should also use the most up-to-date principles available to insure that roadways are not overly lit.

Light Rail Transit

Light rail transit (LRT) has emerged as a form of rail transit designed for trips inside a city and/or trips linking suburbs and the urban core. Light rail use has followed the rising costs associated with oil as a fuel source, postwar increases in automobile ownership and resultant congestion, and an increased premium placed on coordinating transit with other planning goals.

New LRT systems developed in the United States because of innovations made by local transit advocates and planning agencies, with inspiration taken from Northern European systems. Cities have chosen light rail as a less costly alternative to subways and in response to real estate interests or residents who want to promote less car-dependent neighborhoods. Often LRT planners seek gains from transit-oriented development or by linking transit and growth goals to support central business district (CBD) development.

Not all regions have been equally successful with LRT. Regions with the greatest success in attracting passengers and transit-related growth have made planning decisions to tie LRT to increasing urban density and have located light rail near transportation focal points. Studies comparing LRT to other transportation modes have noted LRT's advantages in speed, cost and sustainability, but some researchers have also taken issues with various claims.

Definition

LRT is a public transport system that uses steel-tracks on a fixed guideway, generally operating using exclusive rights of way and vehicles that can operate as multiple units coupled together or as single units. Sometimes LRT tracks can overlap with city streets, sharing traffic with cars and other vehicles. Light rail systems are usually at surface level, but they sometimes operate within systems with underground, or subway, stations and sections. For example, about 80 percent of Buffalo, New York's LRT system is underground.

Although heavy transit systems—popularly known as subways, metros, or undergrounds—generally have greater operating speeds than LRT systems, the LRT can save passengers time through reduced boarding and exiting times, and stations can be closer to destinations, leading to shorter commuting times. Planners must decide between

having more stops, which provides better access to buildings and homes in dense downtown areas, or fewer stops, which decrease total commuting time for those living in outlying areas.

A variety of different specific technologies are being used by different LRTs around the world. In Portland, Oregon; and Boston, Massachusetts, a part of the system involves underground stations. In both Portland, Oregon; and Stockholm, Sweden; the light rail system interfaces with street traffic in some areas, even though each system primarily travels on a dedicated right-of-way separated from street traffic. In the United Kingdom, the Docklands Light Railway (DLR) in London is a fully automated system with cars powered by an electrified third rail, a power source usually used by traditional heavy rail systems.

The Rise and Fall of the Streetcar

In the *Light Rail Developers' Handbook*, Lewis Lesley compares light rail to streetcars and traces them back “to medieval mines in Europe, where beams of wood were laid longitudinally to make the haulage of wagons easier. These “traams” or wooden balks lent their name to tramways. Later, iron plates were used on the timber beams to increase life and give a smoother haul, and with the advent of iron rails and steam haulage came railways.”

Lesley states that the birth of light rail can be dated to 1832, when the first street railway was laid on 8th Avenue in New York City. Urban streets in those days were then mainly plain dirt that turned to mud in rainy weather. With the addition of rails, the load a horse could pull along those streets was increased eightfold, he notes. Other North American cities developed their own horse-drawn street railways, and the first European system opened in England in 1860.

Starting in the late 1920s, cities began switching from streetcars to buses. The advantages were that tracks no longer had to be maintained, one mechanical failure would not shut down an entire line, and buses were easily rerouted if demand shifted or a street was temporarily blocked by a fire or another emergency. The initial investment cost for a bus was also far lower than for a streetcar.

Although transit companies tended to think about the lower capital investment in buses versus streetcars, the cost of operating buses was actually higher over the long term and they wore out

sooner. While buses needed replacement after only six to eight years, streetcars could easily run for decades.

The decline of streetcars is evident in the numbers. In 1930, there were 55,150 streetcars, 173 trackless trolleys, and 21,300 motorbuses in the inventory operated by U.S. transit companies. In 1960, there were only 2,856 streetcars, 3,826 trackless trolleys and 49,600 buses.

While buses may have replaced streetcars because of their lower capital costs and greater route flexibility, history also includes questions about the role of such companies as Firestone Tire, General Motors (GM), Phillips Petroleum, and Standard Oil of California—all of which had more to gain from the rise of bus transportation than the continued use of streetcars.

During the late 1930s and most of the 1940s, Firestone, GM, Phillips and Standard Oil of California were equity investors in a holding company, National City Lines, Inc., which acquired local transit companies all over the United States, amassing almost 50 systems by 1947. From 1947 through 1949, an antitrust suit, *United States v. National City Lines, Inc.*, moved through various federal courts, including the U.S. Supreme Court, before the companies were convicted in 1949 of creating a monopoly to supply equipment, fuel, tires and other products to the transit systems.

The holding company was dissolved, but by that point, the conversion from streetcars to buses in transit systems was largely complete across the country. Only a few large cities—including Boston, Massachusetts; Philadelphia and Pittsburgh, Pennsylvania; Newark, New Jersey; San Francisco, California; and Toronto, Ontario—continued to operate streetcars. They survived for a variety of reasons, but their success rested largely on their ability to move people much more quickly than any transportation mode using surface streets because of their reserved rights-of-way and tunnels.

Light Rail Renaissance

The public quickly became disenchanted with the buses that mostly had replaced streetcars. In the 1950s and 1960s, buses were characterized by heavy fumes, jerky starts and stops, slow speeds and general lack of comfort. Soon, passengers abandoned buses for automobiles and mass transit ridership declined.

In Europe, the 1970s represented a turning point as cities began to realize the truth behind the seminal findings of British professor Colin Buchanan's 1963 report, "Traffic in Towns." Buchanan found that the potential demand for automotive travel was so great that even in low-density cities, there would not be sufficient road or parking capacity to meet peak travel needs.

In North America, researcher Gregory L. Thompson traces the origins of the light rail renaissance in the late 1960s and early 1970s to Edmonton, Alberta, and San Diego, California, which were the first cities to adopt light rail in Canada and the United States, respectively. He credits the following for the revival:

[v]isionaries and reformers who, because of globalization, were able to look past the domestic transit industry and its suppliers to more promising offerings from the transit industry in northern Europe.

Thompson writes that a "growing disillusionment with technological progress" and an attempt to move beyond the status quo in transit services led to the emergence of a "light rail movement." North European cities made several innovations, among them the use of large cars with wider doors to handle greater numbers of passengers, enhancements that led to greater rail-car speed, and traffic engineering and infrastructure investments that supported railway development.

Portland, Oregon, became a model for many planners. In 1978, the city banned passenger cars from a 12-block area connected to the two main downtown thoroughfares, thereby encouraging pedestrian traffic and mass transit use. In 1986, a 15-mile segment of a new LRT between Portland and Gresham, a city 16 miles to the east, opened. In 2001, the city built the first major modern streetcar system in the United States. This line did not travel to distant suburbs. Rather, it used shorter trains and focused on the urban core.

Light Rail, Land Use, and Development

LRT has to be considered as part of a larger environmental, energy, economic, and urban system. The U.S. government has supported light rail projects over the last several decades partly because of the ecological and energy-saving benefits. Mass

transit is seen as contributing to improved air quality and energy conservation. The economic and urban systemic aspects of light rail involve not only its costs but also the relationship of this transportation mode and infrastructure to larger development goals a city might have. LRT planners have usually linked transportation planning to other objectives, although the ability to link these goals differs depending on a locality's philosophy, historical circumstances and resources.

The automobile, cheap gas, and rising land values made possible and promoted decentralized spatial configurations, helping lure businesses and jobs from downtown hubs, particularly in the postwar era. In contrast, older cities had previously followed a hub-spoke pattern connecting various suburbs with a CBD. In the early postwar years, from the 1940s to the 1970s, the suburbs and cities competed for some of the same business patrons. Starting in the 1980s, the revival of many CBDs helped fuel the return of urban light rail systems, which often became part of larger redevelopment efforts.

Thompson and Jeffrey R. Brown studied 10 metropolitan areas with LRT, compiling data looking at CBD employment as a share of regional employment from 1970 to 2000. The employment share for the cities decreased significantly in Atlanta, Dallas-Fort Worth and Minneapolis-Saint Paul, but it increased in Denver, Miami, Pittsburgh, Portland, Sacramento, and San Diego. Salt Lake City showed only a slight decrease.

Even though each of these cities has a light rail system, Thompson and Brown found that the type of LRT in each city either supported or discouraged travel into the CBD, with the share of employment following in predictable ways.

For example, localities such as Minneapolis-Saint Paul, Pittsburgh, and Salt Lake City have a CBD-radial transit route model that does not match "the dispersed pattern of destinations to which transit users wish to travel," Thompson and Brown say. Portland and San Diego, meanwhile, performed better in terms of employment growth in the CBD "because their decentralized transit networks match the dispersed pattern of destinations."

Portland and San Diego also performed best in terms of measures of transit riding habits, service productivity and operating expenses per passenger mile. Both cities link LRT and bus service so that

A two-car Tri-Met light rail train runs through southeast Portland, Oregon, alongside a freeway. Portland's light rail transit system has been very successful, with expanded service bringing a 220 percent ridership increase from 1971 to 1996.

each “could leverage one another to more effectively serve dispersed destinations.” San Diego also coordinated a diverse array of transit operations into a unified system that facilitated transfer and coordination among operators and routes.

Robert Cervero also writes about the relationship between light rail transit and urban development:

Since LRT represents a relatively permanent investment along a fixed guideway corridor, it, like heavy rail rapid transit, has the inherent potential to influence urban growth, affect land uses, promote redevelopment, and increase nearby property values. Importantly, since rail systems improve regional access, new growth tends to cluster around station sites, and declining areas can be rejuvenated because of the

higher value and profit potential of the surrounding land.

The relationship between LRT and economic activity has been explained in other ways. Benefits have been linked to more comprehensive planning paradigms. Cervero notes that “building a light rail system won’t bring about major land use changes or stimulate private investments in and of itself; those goals will require plenty of development incentives and a strong public commitment to concentrated urban growth.”

The motivations of localities for developing light rail and the extent to which planners have a comprehensive planning agenda can influence the development potential of LRT. Short-term cost savings can sometimes come at the expense of long-term land development benefits. Sometimes, LRT routes are aligned along abandoned railroad corridors and industrial belts, where land was relatively inexpensive, rather than in mixed-used or denser neighborhoods where land is relatively expensive. When light rail lines are developed on established physical routes, such as former rail lines, even though passenger travel in the present day no longer follows those patterns, the light-rail system by itself will likely fail to raise property values or drive economic activity in the areas surrounding the stations along the route.

A comparison of LRT-associated development outcomes between one of the least and most successful cases in the United States suggests both the limits and possibilities of LRT as a development agent. Buffalo, New York, and Portland, Oregon, are two cities with stagnating downtowns where planners saw LRT tied to pedestrian transit malls as a way to ignite a revival. By the third quarter of 2012, the ratio of transit trips to the population of metropolitan Buffalo was 2.0 percent, in comparison to 5.8 percent for metropolitan Portland.

In Buffalo, the Department of Community Development became the lead agency in a comprehensive effort to establish a viable downtown core and reverse the exodus of retail stores from the CBD. Buffalo invested in a new downtown civic center and an office/hotel complex, as well as a LRT to service these developments, with the goal of creating 6,700 jobs for the depressed city. After construction of a costly underground system, Buffalo opened its LRT in May 1985. The Buffalo Metro line was faced

with the threat of a shutdown after the first year because of major operating deficits and ridership only a little more than half of what was predicted. Fares paid for less than 20 percent of the Metro's operating costs.

Portland rolled out its LRT in phases after a less costly bus transit system helped promote rights-of-way and ridership. Planners developed a Transit Investment Corporation to leverage private capital through various public improvements and to manage mixed-use joint developments around stations.

As G. B. Arrington describes it, Portland's city center planning model focused "the most intensive development adjacent to transit," with mixed-use development at pedestrian scale. The city placed strict limits on commuter parking and limited the addition to road capacity serving the downtown to discourage cars and encourage transit ridership. Portland also installed "an urban growth boundary . . . that legally defines what's urban and what will remain rural."

From 1971 to 1996, Portland's regional transit agency Tri-Met expanded service by 140 percent and saw an increase in ridership of more than a 220 percent. By 1996, roughly 40 percent of downtown work-related trips included the use of transit. One study published that year reported that improved transit access, together with extra housing and other improvements, helped increase the downtown district's share of the metropolitan area's total retail turnover from 5 percent to 30 percent.

Decline of traditional manufacturing hurt Buffalo but spared Portland, a city tied to more dynamic high-technology sectors. Cervero concluded, "For LRT to have an extensive impact on urban form, a strong and growing regional economy is an important prerequisite." Yet, Thompson also shows that transit planning can be an independent variable, such that even fast-growing cities can choose less successful LRT configurations.

Cervero noted that San Diego's system increased downtown retail sales at the expense of border communities, meaning that LRT can redistribute business activity without necessarily fueling growth. Other planners argue LRT's primary goal is to compete with car trips and serve areas that have established high levels of employment and car use but that LRT can't autonomously trigger a regeneration process.

Sustainability

Cervero summarized various advantages of LRT compared to other modes:

[LRT] is relatively quiet, thus environmentally unobtrusive; is electrically propelled, thus less dependent than buses on the availability of petrochemical fuels; and can operate effectively along available railroad rights-of-way and street medians, thus is far cheaper, less disruptive, and easier to build than heavy rail.

This assessment was before bus rapid transit (BRT) emerged as important in discussions about new forms of mass transit system delivery. Some studies have argued that BRT provides higher performance and significantly lower costs per passenger trip in medium- and low-density cities.

However, Thompson and Brown's later review of different cities and studies found "no meaningful difference in the capital expenses per passenger miles between cities choosing to invest in bus rapid transit facilities and those investing in light rail facilities." The authors note that express buses on high occupancy vehicle lines typically can't provide certain forms of regional connecting service "because they usually lack the stops for accessing regional destinations and for providing transfer opportunities."

LRT systems have been able to provide such linkages. In Sweden, the successful Tvärbanan LRT system in Stockholm uses specially dedicated bridges, tunnels, and rights-of-way to connect commuters from transit lines and commuters using heavy rail lines or buses following a traditional hub-to-spoke (downtown to outlying residential area) pattern.

John M. Stutsman's study of Los Angeles transit systems indicated that LRT was "environmentally superior to BRT (especially in relation to noise and traffic impacts)" and had "more new daily transit riders," but BRT was "somewhat more cost-effective."

Using a different methodology, Richard Stanger's study of Los Angeles regional transit found that the Blue and Gold LRT lines had an average travel speed 40 percent greater than the Orange Line busway's speed, even though the bus has an exclusive right-of-way for 90 percent of its length. The operating cost was \$0.46 per passenger mile for rapid buses, \$0.53 per passenger mile for the Freeway Busway, \$0.48 for the Orange Line, \$0.42 for rapid

transit (the heavy rail metro) and \$0.50 for LRT lines. The subsidy was \$0.46 per passenger mile for rapid buses, \$0.45 for the Freeway Busway, \$0.36 for the Orange Line, \$0.29 for rapid transit and \$0.41 for light rail lines.

A national study by Edson Tennyson found in 1989 that rail transit was “likely to attract from 34 percent to 43 percent more riders than will equivalent bus service.”

Lewis Lesley notes that cost discussions must also figure in the potential role played by development:

The first stage of London Docklands light railway, which opened in 1988, was paid for within three months of the start of construction, through the rise in the value of brownfield sites and land sales.

Yet, he explains, not all regions would be able to capitalize on overheated land values.

Cities such as Pittsburgh in the United States and Manchester in the United Kingdom are viewed as post-industrial cities that have had success in building a growth model supported by LRT. Yet, the greater Portland region also has leveraged its local capacities in LRT as a transit service to also support a relatively new manufacturing effort to build streetcars.

Light-Duty and Pickup Trucks

Light truck is a U.S. legal and industry classification for motor vehicles. Title 40 of the Code of Federal Regulations defines light truck as designed primarily for purposes of transportation of property or [which are] a derivation of such a vehicle, designed primarily for transportation of persons

with a capacity of more than 12 persons, or available with special features enabling off-street or off-highway operation and use, where such vehicles have a gross vehicle weight rating of no more than 8,500 pounds. The legal classification includes pickup trucks, sport utility vehicles (SUVs), and vans, and groups together those trucks that are similar enough to automobiles to not require a separate driver's license classification. Buses, larger trucks, and other commercial vehicles are covered under the requirements of the commercial driver's license.

The "Chicken Tax"

Vehicles are classified not just for licensing purposes, but also for taxation and sometimes surprising policy purposes. For instance, the "chicken tax" is a steep 25 percent tariff on imported light trucks with an interesting history and lasting effect.

The odd-sounding tax takes its name from a ban on American chicken imports by France and Germany in the early 1960s, when a revolution in American poultry farming had made U.S. chicken the cheapest on the world market. As a punitive response, in 1963 President Lyndon Johnson imposed a tariff on imports of some of the major goods France and Germany exported, including brandy, dextrin, potato starch—and light trucks. The tariffs on brandy, dextrin, and potato starch have since been lifted, but the light truck tariff has remained for 50 years, even though there is little rationale to preserve the tariff today.

The release of recordings from the Johnson administration has since revealed that the stated issues with France and Germany were never the real reason for the light truck tariff. Rather, it was developed as part of Johnson's discussions with the United Auto Workers (UAW) union and the possibility of a strike, which would have put Johnson at a disadvantage when seeking reelection.

In return for not striking, the UAW wanted something done about Volkswagen's aggressive attempts to command a larger share of the U.S. market. The resulting chicken tax reduced the price advantage of Volkswagen vans. Because the chicken tax did not specify a country of origin for its tariff, it later made it more difficult for Japanese and other foreign manufacturers to compete in the light truck category with American manufacturers. This is one reason why the pickup truck category has been

dominated by American manufacturers in subsequent decades, even as imported passenger cars have become more common.

Foreign companies have made repeated attempts to find loopholes in the tariff. Japanese manufacturers for a time imported trucks into the United States without truck beds or cargo boxes, which were attached by the retailer before sale. This loophole was closed in 1980. At one time, the Indian manufacturer Mahindra and Mahindra had a plan to export its light trucks to the United States in the form of kits to be assembled by the retailer, although that idea was tabled. Even U.S. automaker Ford has had to make adjustments. It imports trucks from its plants in Turkey that are equipped with rear seats to qualify them as passenger vehicles. The seats are removed after importation and the vehicles are then sold as pickups.

One of the reasons the light truck classification uses transportation of property as a criterion is that many regulations presume that light trucks are used more for practical or work purposes than as personal transportation, while cars are used principally as transportation of passengers. This presumption has, of course, been challenged; many pickup trucks are used both for utilitarian reasons, such as transporting goods that are not possible or practical to transport in a car, as well as for personal transportation. Another angle on the discussion revolves around minivans and SUVs, which are used and marketed as having truck-like utility. Further, manufacturers question whether utilitarian vehicles should be subject to different regulations than those for personal transportation.

CAFE Standards

One area where the classification of a vehicle has broad financial implications for automakers is in compliance with the Corporate Average Fuel Economy (CAFE) standards, introduced in 1975 when volatile oil prices and the maturation of the environmental movement coincided to bring about a new level of concern over fuel efficiency. CAFE standards are not based on individual models, as emissions and safety standards are, but on the average fuel economy of a manufacturer's entire current-model-year fleet.

For CAFE, the fuel economy of all of the vehicles in a given class sold by the manufacturer in that model year is averaged out. If that average fuel

economy does not fall within the specified standard for the vehicle class, the manufacturer pays a penalty based on the number of 10ths of a mile-per-gallon that the manufacturer's total production for the domestic market varies from the standard. Since 2011, the fuel economy standard to which manufacturers' averages are compared has been derived from a mathematical formula that depends principally on the vehicle's footprint.

The larger the footprint of the vehicle, the lower the fuel-efficiency standard to which it is held—and the easier it is for manufacturers of larger vehicles to avoid costly penalties. Light trucks are also exempt from the Gas Guzzler Tax, which is assessed on passenger cars with a tested fuel economy of less than 22.5 miles per gallon.

Safety

Traffic fatalities are the leading cause of death for Americans under 40, and conventional wisdom has long held that heavier vehicles are safer for their occupants. The National Highway Traffic Safety Administration (NHTSA), which regulates CAFE standards, has advocated this belief and expressed concern over federal efforts to encourage greater fuel economy. In the NHTSA's view, lighter vehicles are more fuel-efficient, but they are also more dangerous vehicles. Although this perception is not the source of the separate fuel-efficiency standard for light trucks, it has, in effect, encouraged light truck ownership and deterred the development of more fuel-efficient light truck designs.

However, studies conducted in the wake of tremendous growth of American truck ownership have suggested that light trucks do not necessarily adhere to the heavier-is-safer rule. Their maneuverability and braking are markedly worse than comparable automobiles, and their higher center of gravity makes rollovers more common.

Further, the benefits of their greater size and weight apply only to the light truck's own passengers, making accidents involving these vehicles more dangerous for the occupants of most passenger cars. Now that light trucks represent half the number of the vehicles on the road, this has become a significant factor in overall road safety.

Automobiles are designed to prevent the passenger cabin from being penetrated in a collision, but the safety features protecting the cabin assume a collision with another automobile. Trucks,

however, ride high enough to bypass the safety bumper that is designed to keep colliding vehicles from penetrating the cabin. Further, heavier trucks may have a sturdier construction, but that also means they exert more force than a lighter vehicle during a collision. All other factors being equal, then, truck-car accident can have results much more damaging and severe than a car-car accident. A study by the National Institutes of Health found that the net effect on road safety is negative—more trucks mean more fatalities—and the fatalities are disproportionately distributed, with about 80 percent of them affecting occupants of the nontruck vehicles.

Liquefied and Compressed Natural Gas

Liquefied natural gas (LNG) is natural gas that has been liquefied for storage, whereas compressed natural gas (CNG) remains in gaseous form, although it is compressed to a fraction of its natural volume so it can be stored and transported in cylinders exerting pressure of 3,000 to 3,600 pounds per square inch.

Natural gas is a hydrocarbon gas that occurs naturally deep underground, especially in proximity to other hydrocarbon deposits, such as crude oil and coal. Consisting mainly of methane, natural gas includes nitrogen, hydrogen sulfide, carbon

dioxide, and a number of other chemicals, and is generally called natural gas in order to differentiate it from other gases and from gasoline. Natural gas is commonly used in the United States as a heating and cooking fuel, and it can also be used as an alternative vehicle fuel to gasoline or diesel. Natural gas is simply called gas in English-speaking countries outside the United States, where gasoline is called petrol.

Natural gas is a frequent by-product of oil drilling. It used to be burned off at the oil field in order to dispose of it, because of the difficulty of transporting it to a market at an efficient cost. Today, pipelines exist to transport even nonliquefied natural gas to markets, because natural gas has become so valuable as a fuel.

Biogas is natural gas produced through the anaerobic decay of nonfossil matter rather than through the thermogenic processes that create natural gas deep underground. Biogas is naturally formed within swamps and marshes, as well as produced within landfills, where its presence can be a hazard if it is not harvested, and masses of sewage, where it is a byproduct of decay processes.

Natural gas is fairly well exploited in the United States, except where conditions make harvesting too difficult to be cost efficient. Biogas, however, often goes unharvested. Most landfill gas is just burned off in controlled fires in order to reduce the possibility of uncontrolled explosions. Biogas produced as a byproduct of sewage treatment is an exception, and such gas is often used in electricity generation.

Hydraulic “Fracking” Controversy

Natural gas contained in formations of shale, a sedimentary rock of mineral flakes and particles embedded in mud, is called shale gas, and it has become the fastest growing source of natural gas. Historically, shale gas has proven difficult to extract, with the cost of extraction exceeding the value of the gas. Commercial shale gas production didn't begin until the 1970s, when the decline of other natural gas reserves and the energy crisis of that decade made it appealing.

Tax credits and government grants for shale gas extraction research fed the industry for some time, but shale gas exploration really took off in the 21st century, climbing from 1 percent of U.S. natural gas production at the dawn of the century to 20 percent by 2010. It is expected to account for half of natural

gas production by mid century. Shale gas production is accomplished through hydraulic fracturing, or “fracking,” which uses a pressurized liquid to fracture the rock layers in which the shale gas is contained to release the gas for extraction.

The vast majority of fracking is done in the United States, but the environmental and health consequences have invited controversy. Critics contend that fracking compromises the quality of underground water supplies, consumes vast amounts of water at a time when droughts are a recurring problem in parts of the country, releases greenhouse gases into the air, and requires more energy in the extraction than the gas itself yields once extracted. Significant concerns have also arisen around small earthquakes induced by fracking, as well as the radionuclides associated with and released by the process that may introduce radium to the water supply, and the disposal of toxic fracture fluid after use.

In many circles, the production of shale gas by fracking is believed to have a greater negative environmental effect than the energy benefit of gas production. The health consequences are seen as significant, especially given the proximity of many fracking or potential fracking sites to human settlements. Air and water pollution are allegedly becoming much more severe, and carcinogens and toxins that can lead to chronic illness are being introduced, critics say.

In response to the concerns raised by fracking in the United States, other countries have begun banning the process, and it remains unclear how stricter regulation, if it occurs here, will impact the economic feasibility of shale gas production. The capital investment in shale gas production equipment—as well as in other natural gas exploration, production, and processing technologies—depends on the natural gas extraction being profitable in order to be worthwhile. Although many experts believe that the natural gas reserves in the United States would take a century or more to deplete, recent research has suggested the possibility of a deliverability crisis in the near future as resources become increasingly expensive to access.

Processing Natural Gas

Whatever the source of natural gas, like other naturally occurring hydrocarbons, it is processed before it is usable as a fuel. Processing removes water vapor, impurities including radioactive gases and mercury,

A member of the U.S. Navy fills a government vehicle with compressed natural gas (CNG) from a naval base fuel supply in Jacksonville, Florida, August 2005. Lack of access to many CNG refueling facilities may limit private use of CNG vehicles.

and heavier hydrocarbons such as propane and butane, which have their own industrial uses. The end product is a gas that is primarily methane with a mixture of nitrogen and carbon dioxide.

Liquefied natural gas is often confused with compressed natural gas, the form of natural gas used as a vehicle fuel. However, LNG refers only to a specifically prepared form of natural gas that remains in liquid form only for the purposes of transport and storage.

LNG is produced primarily overseas, where production occurs in order to transport the natural gas to a place where it can be sold. The gas is liquefied by cooling it to minus 163 degrees C (minus 261 degrees F). LNG is produced mainly in Qatar, Russia, Indonesia, Algeria, Brunei, Egypt, Malaysia, Nigeria, Australia, and the United Arab Emirates. From there, it is transported to LNG-receiving terminals in 18 countries. It is transported by specially designed LNG tanker ships, which are equipped with four to six tanks surrounded by ballast tanks and voids.

CNG is a natural gas that has been compressed for use as a fuel, but not to the same degree as LNG, which has been compressed for transport. CNG can be used in internal combustion engines and is often used in bi-fuel engines, which are capable of running on two fuels, one being diesel or gasoline

and the other being an alternate fuel such as CNG, liquefied petroleum gas or hydrogen. In much of the world, CNG is beginning to be used in larger vehicles such as buses and trucks. It can also be used in locomotives. Because these larger and heavier vehicles consume more fuel, the cost of conversion to bi-fuel is more quickly returned than in a smaller automobile. However, Volkswagen, Toyota, Honda, Peugeot, and Fiat all manufacture bi-fuel cars for some markets.

CNG is a cleaner fuel than gasoline, although it does emit some greenhouse gases. Because it is leadless and free of benzene, it does not create lead buildup on sparkplugs as gasoline does, nor does it contaminate crankcase oil. CNG has a narrow range of flammability, which makes explosions in accidents less common. Its pollutant levels of carbon dioxide, carbon monoxide, unburned hydrocarbons, nitrogen oxides, sulfur oxides, and particulates are lower than for gasoline. However, whether CNG usage results in lower in greenhouse gas emissions over the life cycle of the fuel being used depends on how the CNG is produced. When dirtier methods of fuel production are required to offer a fuel that is cleaner to use during the consumer's usage, environmental gains may be small, if any. That said, there are economic as well as environmental motives for natural gas use, and not every method of natural gas production has the same level of environmental impact as fracking.

The drawback to CNG as an automobile fuel is that natural gas takes up more space than the equivalent amount of gasoline or diesel. Larger vehicles can accommodate this without much difficulty. Some CNG-burning buses use rooftop tanks, for instance. Factory-built bi-fuel cars typically use tanks on the underside of the vehicle, which is common in Volkswagen's bi-fuel vehicles, for instance.

Drivers who convert their existing cars to CNG must find another solution, usually installing a CNG tank in the trunk of a car or the bed of a truck to reduce the storage space. For this reason, CNG usage is not as appropriate an alternative for as many vehicles as biodiesel and gasoline-ethanol mixes. Also, as with other alternatives to gasoline use, the use of the vehicle is dependent on an available source of fuel. While transit companies can maintain their own tanks of CNG, this tends to be impractical for most private individuals.

The greatest concentration of CNG-using vehicles is found in countries where natural gas is produced, including Iran, Pakistan, India, Brazil, and Argentina. CNG taxis are common throughout South America, and Argentina and Brazil have the world's largest fleets of CNG vehicles for this reason, with significant numbers in Colombia and Peru, as well. Singapore, which pioneered the use of CNG in public transit and delivery vehicles, has seen a rise in the use of CNG in private automobiles driven by rising gasoline prices and growing awareness of CNG as an alternative. The government of Singapore offered a rebate to new owners of green passenger vehicles, including CNG cars, from 2001 to 2012, contributing to the growth of the sector.

The United States has actively encouraged natural gas as a vehicle fuel, but the number of natural-gas-using vehicles barely increased from 2000 to 2010. Thirty-four states have at least one CNG fuel station, and CNG often costs about half the price of gasoline, but it remains a niche market. Transit companies and government bodies in California, Massachusetts, and Pennsylvania have converted portions of their fleets to CNG.

Livable Streets

Livable streets are particular forms of transportation infrastructure that account for transportation, land use, housing, and environmental challenges in an integrated and balanced manner to improve the quality of life for a community. In this regard, livable streets can enable context-specific mobility solutions to promote the economy, social well-being, and the environment for different communities in a metropolitan area.

Livable streets can improve the economic livability of a community by providing the means for reliable, affordable and safe transportation that supports the connection of affordable housing with jobs that provide livable wages. Moreover, livable streets can advance a community by supporting transportation designed to sustain public health, personal security, traffic safety and social interactions. In addition, livable streets can improve the environmental livability of a community by positively affecting neighborhood cleanliness, traffic noise and air quality.

Decisions and policies that foster the design and implementation of livable streets are ones that incorporate important aspects of human thriving. Determining what makes streets livable is a difficult task because it involves a degree of subjectivity. Therefore, community leaders, planners, and policy makers need metrics to identify and quantify the elemental attributes of livable streets.

Livable Transportation Systems

In an urban area, livable transportation would make it feasible and safe for people to walk or bike to important amenities, take public transit to work or recreational destinations, and to be able to afford and park a car. In a suburban setting, car ownership is often essential, and livable transportation would allow people to drive safely within a reasonable amount of time to important destinations, to possibly take a commuter train to work, and to walk or bike safely.

Livable transportation systems have the potential to facilitate the achievement of numerous community goals by providing better access to jobs, community services, affordable housing, and schools. To this end, communities need transportation facilities and services of the right quality, location, and type. Communities, businesses, and consumers all benefit from livable transportation systems.

A transportation network designed to make streets livable will take a wide variety of modes into account while encouraging patterns of development that are sustainable. Livable transportation systems can also improve community safety and appearance, and reduce environmental impact, by decreasing energy use and using land more efficiently.

Livable Versus Sustainable Transportation

Because it deals with the quality of life for a specific community in the present and near future, livable transportation is more place-based and near-term-focused. It addresses human concerns such as choice in transportation and housing, as well as access to employment and education facilities. Sustainable transportation is concerned about meeting today's needs without preventing tomorrow's citizens from meeting their needs.

There are distinctions between livable and sustainable transportation systems, although both encourage travel options that are more environmentally sustainable and promote economic development. They also both affect human health, although livable transportation is more about active living and sustainable transportation is more about air pollution impacts. Livable and sustainable transportation systems have policy impacts related to social equity for low-income, young, old, disabled, and minority groups.

Yet, livability and sustainability in transportation systems can sometimes be at odds with one other. In 2009, the U.S. Department of Transportation conducted an Omnibus Household Survey on Public Perceptions on Transportation Characteristics of Livable Communities. While survey respondents said they considered multi-modal and non-privately operated-vehicle (POV) transit, such as sidewalks, bike lanes, and local transit, to be important, they still considered POV facilities, such as major roads and adequate parking downtown, as more important.

Livable transportation is enhanced, consumers were saying, by owning a car and being able to use it freely. From the viewpoint of sustainable transportation, however, these consumer sentiments would be outweighed by the environmental impact of driving a car, which leads to increased gasoline consumption, greenhouse gas emission, and climate change. The challenge for planners is to balance these conflicting forces in ways that enhance

quality of life in the community without degrading the environment.

Transportation Planning Process

One of the goals in urban planning is to make communities more livable. This encompasses numerous elements, including transportation, its systems, and its infrastructure. During the planning period, transportation practitioners engage other stakeholders to form forward-thinking ideas, address broad issues, develop understanding of potential outcomes and choices, and develop integrated solutions for the long term. New planning and process methods help incorporate livability goals, integrate mobility with other community needs, reach more participants, develop creative plans, and help align fiscal realities to actual transportation costs, thereby improving project delivery.

Updated policies can help integrate livability goals across the spectrum of a transportation agency's projects, but bringing about such changes requires political backing, buy-in from staff and leadership, and strong external partnerships. Such partnerships can involve public, private, and nonprofit agencies, all of which can help meet funding, policy, program, or planning goals. Designing for livability necessitates knowing those who plan to use the system by integrating their input throughout the design process. Coordinating transportation investments and livability goals can improve performance of the system and leverage more funding.

Land Use as a Supply-Side Factor

The supply-side factors that affect transportation and livability include land use, urban design, and roadways. Land use is an important factor because land-development patterns influence transportation patterns, and transportation patterns influence land-development patterns. More specifically, land-development patterns influence where a person lives, works, goes shopping, socializes, and exercises. Transportation patterns influence how people get to and from these places, the travel mode they use, the length of time it takes, and the expense incurred. These factors are significant in determining the livability of a place, as well as its transportation infrastructure, including its streets.

Transportation and livability vary from place to place, and from land use to land use. In a dense urban setting with a mix of commercial spaces and

residences, a livable transportation system would be different from that in a less dense suburban setting where land uses are more separated. That setting, or context, has an influence on how people travel. Overall, a community with many destinations in close proximity also provides people with more options about which transportation mode to use. In such a setting, livable transportation may look like biking to the store, walking to the bus stop to go to work, and driving to a theater to see a play.

In a community with fewer destinations accessible nearby, people have fewer options about transportation mode choice. In this type of setting, livable transportation may look like being able to drive to the store easily and park without a hassle, to drive to work without too much congestion, to possibly take commuter rail to work because there is a station nearby, and to walk or bike to the local park to enjoy a weekend afternoon. Land use does not dictate what transportation options a person has, but it does significantly influence them.

Urban Design as a Supply-Side Factor

How the space is designed determines how land is used. Urban design deals with how buildings are arranged, parks are located, and streets are laid out. Urban design influences transportation because it deals with street design, from how wide streets are and the pattern they take to how they connect to other streets and how well-suited they are for walkers, shoppers, and bicyclists. These are all factors that affect the transportation network and the livability of the community that transportation network serves.

Urban design also deals with the streetscape, how the street looks, is structured, and what features are present. This can include the width of the sidewalk, planting of street trees, location of signs, width of traffic lanes, inclusion of bicycle lanes, presence of a median, and placement of parking. These factors, and others, make up the streetscape and can have a significant impact on the livability of a community. Streetscape considerations help determine whether streets and sidewalks are safe for all users, how attractive an area is, whether people want to be out on the street to interact with neighbors, and how local businesses are situated and accessed.

The effect of urban design on livability depends significantly on the context. A gridded street network in a dense urban neighborhood is likely to

promote transportation choices and be more livable. A cul-de-sac-type layout in a low-density suburb is likely to meet the preferences of the residents there, even though it could impede travel in some ways. The streetscape of a community significantly influences the travel that occurs there and the social and economic vibrancy of a place, too. As transportation-related livability factors vary from place to place, so, too, do the urban design factors necessary to make a place livable.

Roads and Highways as a Supply-Side Factor

A dense road and highway network means that destination accessibility by road is very high. A person can use a road to travel almost anywhere. Roads enhance mobility, the ability to travel to destinations quickly. Accessibility, which is the ability to get to destinations, and mobility, which is the ability to get to destinations quickly, both significantly improve livability.

Planning, design, and construction improvements can help improve roadway capacity issues, providing congestion relief, especially during peak hours. Road congestion harms livability because it delays, and often frustrates, drivers. Traffic congestion also increases emissions and fuel use.

One possible solution to congestion would be new road construction, but in many cases, especially in urban areas, there may be no room to build new roads or add lanes to existing highways. In these cases, transportation agencies use strategies such as travel demand management, which encompasses a variety of efforts including carpooling, telecommuting, congestion pricing, biking, walking, and shifting mode share from car to transit.

Agencies can also improve system efficiency through management and operations strategies, which can include access management, intelligent transportation systems, incident management, and freight and goods management. The roadway network is an essential part of the transportation system, and it needs to be well managed to operate efficiently and to provide livable conditions for all who use it.

Roadways are not only conduits for cars to get from one place to another; they are also a major part of the physical environment of communities and a significant factor in how people feel about their communities. The same person living in the same house will likely feel very different if the house is

next to an expressway as opposed to being next to a gravel road.

Studies have shown that streets affect feelings of safety, social interactions, and physical awareness of one's surroundings. Busy streets are less livable for the people living alongside them. Livable streets, on the other hand, act more like an extension of the residences nearby. Cars can travel along livable streets, but physical features can be designed to cause cars to slow down, making the streets more livable for residents. Such streets can have multiple benefits for residents with respect to safety, health, community, and property values.

The environmental impacts of paved roads can also be significant. The impermeable surface that pavement creates prevents water from naturally soaking into the ground when it rains. Normally, this runoff is handled by a city's storm water system, but paved surfaces can increase the likelihood of flooding. Pavement also can be a factor in creating an urban heat island, where the pavement absorbs heat during the day and releases it at night; this can be particularly problematic during summer months when heat turns ozone into smog.

Efforts are underway to address environmental problems associated with roads. The sustainable streets movement seeks to reduce the environmental impact of paved streets, among other goals. To manage storm water runoff more effectively, some streets are now made with permeable paving material that allows some water to seep through to the soil below. Sustainable streets also might incorporate landscaping features that allow some storm water to run off into planter boxes along the roadway. This helps manage the volume of water flowing through the storm water drain system.

Sustainable streets are able to mitigate the urban heat island effect through the planting of trees and other vegetation along the road or down a median in the road. By shading the roadway and preventing it from absorbing as much heat, plants have a natural cooling effect. Roads can also be constructed with lighter colored materials, such as concrete rather than asphalt, to help reflect the sun's rays rather than absorb them.

Sustainable streets, therefore, improve livability by reducing flooding and its associated damage, decreasing heat to reduce air conditioning costs and smog-related health problems, and improving aesthetics through the presence of trees and plants.

Although roadways are primarily built for automobiles, they can contribute to the livability of communities when the transportation needs of all users are considered during the design and planning. This means making streets safe, practical, and attractive not just for cars but also for walkers, bikers, and transit riders. This method of "complete streets" planning can have many benefits.

When a family can get to some of their important destinations without having to use a car, it could become possible for them to reduce their car ownership, which is typically a significant portion of a family's expenses. Complete streets make it safer and easier for both the young and old people to get around, freeing them from depending on someone else for a ride. Complete streets can benefit drivers, too, by making roads safer and reducing the number of cars on the road as more people walk, bike, or take public transit.

These well-managed, livable, sustainable, complete streets cannot be built all at once, however. In the meantime, transportation agencies can enhance their roadways by selectively choosing where to target their investments. A traffic bottleneck, for instance, could be eased by adding an additional lane, if possible, or implementing a congestion pricing system to shift the demand. Streets do not need to be ripped up just to put in permeable pavement; it could be done when a street is already scheduled for reconstruction. Some aspects of the livable streets concept could be tried on a limited number of streets to see how people respond. If those measures prove successful, livable streets could be implemented on a wider scale. Each of the actions along the way had the possibility of enhancing livability, and, collectively, they could make a significant impact.

Demand Side Factors

In addition to the three main supply-side factors—land use, urban design, and roadways—demand-side factors also affect livability and transportation. Demand-side factors can also be characterized as modal factors or choice in transportation mode. For people, livability improves when they have convenient access to a mode of transportation that fits their needs and is safe and affordable. Choices about the mode to use can be made at an individual level, but decisions must be made at the community or regional level to make

the modal transportation choices available and safe in the first place.

Cars as a demand-side factor. Since roads are so ubiquitous and cars have the ability to access destinations served by roads, cars have a high degree of accessibility. Drivers can go just about anywhere they want to, even though their usual travel is within a relatively short distance from where they live. Drivers can generally travel to their destination at a faster rate by car than by any other mode. The speed of cars makes them highly mobile. This combination of mobility and accessibility means driving is generally convenient and saves a traveler time. All of these attributes enhance livability.

It is advantageous to own a car for the sake of employment, too. In general, when controlling for socioeconomic and demographic characteristics, car owners make more money and have more work hours per week than those who don't own cars. Similarly, participants in the welfare-to-work program are more likely to be employed if they own cars. Employment is a significant aspect of livability, so it would seem that car ownership could be connected with livability for this reason.

From a livability perspective, cars are a positive factor, but, of course, there are downsides. The cost of owning, insuring, licensing, registering, maintaining, parking, and fueling a car can be burdensome. Driving can be stressful, and longer commutes have been shown to lower the commuter's subjective well-being. While car crashes can have a negative effect on a victim's health, and sometimes lead to fatalities, cars are also hazardous when they are being driven safely. They contribute to air pollution and global warming by producing exhaust gases that include ozone, particulate matter, nitrogen oxides, carbon monoxide, and carbon dioxide.

Transit as a demand-side factor. The benefits of using public transit can be significant for both users and nonusers, and those benefits contribute to the livability of the communities where it is available. Transit provides mobility for people who cannot drive or are unable to afford a car, while lessening road congestion for drivers by providing alternative transportation for potential car users. Public transit allows riders to be more efficient, giving them the opportunity to catch up on reading, writing, checking email or social media on a smartphone,

This street in the High Point neighborhood of West Seattle, Washington, incorporates wide landscaped swales that catch stormwater runoff from the paved road surface.

or simply relaxing. Moreover, transit out-of-pocket costs are significantly lower than owning and driving a car.

Beyond individual communities, public transit can improve livability for a large metropolitan area or a whole region by providing an affordable network of transportation options, reducing pollution, cutting down road congestion, and fostering the development of both residential and commercial construction around stations.

The downsides of public transit include the inability of fixed-route systems to access as many places as private automobiles, crowds during peak hours, and comparatively slower travel times in comparison to private cars, although that is not always the case. Express trains and buses, for example, can easily move people more quickly to suburban destinations during rush hours than cars.

Bicycling and walking as demand-side factors. When bicycling and walking are safe, viable, and attractive options, they can be excellent modes of transportation and enhance livability for individuals and communities. The cost of biking and walking are negligible, in most cases, and these forms of "active transportation" have been positively correlated with improved health and negatively

correlated with obesity and diabetes. Not only does active transportation improve the health of the people who are bicycling and walking, it improves the health of the whole community by reducing the pollution that otherwise would have been emitted.

Infrastructure costs and space requirements are lower for bicycling and walking facilities on a per-user basis than for automobiles. Moreover, real estate values may rise for housing near biking and walking trails. Active transportation can also help those who are driving cars by reducing road congestion.

On the other hand, walking and bicycling are more limited in scope than driving and public transit, meaning it is harder to travel as far. Safety concerns, both real and perceived, exist for walkers and cyclists, especially where these people are likely to interact with cars and other vehicles. It is also harder to walk or bicycle in very hilly terrain or when the weather is extreme. These limitations illustrate the necessity to plan and provide facilities for walking and bicycling and also to recognize where these modes fit in the larger transportation system.

Freight as a demand-side factor. While not a mode of travel for passengers, the way freight is transported affects livability. A freight transportation system that operates efficiently is becoming an increasingly important aspect of a successful economic system, and, thus, a livable society. When freight networks, whether rail- or road-based, become congested, substantial delays in freight shipments can harm the economic viability of an area or, in the case of a national network, the entire country.

Other challenges with freight exist. Freight movement, especially in a central business district, can pose challenges for truck drivers, automobile drivers, merchants, and pedestrians. These challenges can relate to safety, pollution, congestion, and logistics. Because it is necessary to deliver goods, freight movement is a consideration for planners when it comes to livability.

Impact Evaluation Issues

The main objective of livable streets initiatives is to improve the quality of life for individuals and the community, while balancing out economic and environmental concerns. The fact that livable streets affect so many aspects of human activity introduces substantial complexity in the measurement of their impact.

Research in the areas of psychology, economics, urban design/architecture, urban planning, sociology, regional science, and transportation reveal that there are significant variations in the interpretation of the terms *quality of life* and *livability*. For example, in the field of urban planning, someone with an urban design background would tend to view livability from an aesthetic perspective, but another person with an economic development focus would tend to see economy vitality as a more significant determinant of livability.

In constructing appropriate indicators to measure livability, a number of issues need to be addressed. While quality of life is measured at the individual level, livability is typically associated with communities. To further complicate the matter, aggregating or averaging individual quality-of-life measures does not necessarily result in an indicator that reflects collective experiences.

In the struggle to reconcile subjective quality-of-life measures for individuals with indicators of the livability of an entire community, the following major issues would need to be addressed in evaluation efforts.

Weighting indicators. While there is no perfect framework to connect quality of life, which is inherently a subjective and personal concept, with the livability of a community, it is clear that measuring livability must take into account heterogeneity in people's preferences and priorities. For example, accessibility to primary education facilities or employment opportunities would have little effect on the livability of a retirement community. One approach to this problem is to give various factors different weights that would account for different preferences of the demographic and socioeconomic groups in the community.

Appropriate scale for analysis. Transit indicators of neighborhood livability, for example, cannot always be scaled up to a regional or state level. Similarly, large-scale indicators are not necessarily relevant at the community level. Even if scaling up or down is possible, it may not make sense from a policy perspective. Within the scope of a transportation demand management (TDM) strategy, for example, "walkability" would be measured only at a local scale and would be relevant only up to a regional scale.

Statistical measurement. What statistical measures would best capture a particular livability dimension? For example, indicators that measure public transportation quality, such as “mean waiting time for service,” are commonly employed. However, from a livability perspective, what is important is not only (or even mostly) the average waiting time but also the distribution of waiting times. If the average waiting time is five minutes but the range of waiting times extends up to 30 minutes or more, the service quality from the community perspective is very different from an individual’s.

Single-sphere versus crosscutting measures. Simply providing indicators related to the economic, social, and environmental aspects of a place would preserve a fragmented view of livability. However, linking indicators through the creation of crosscutting measures might not clearly reveal the preferred direction of indicator change because processes in multiple spheres operate on different scales. For example, measuring bus vehicle miles divided by the number of peak vehicles would create an indicator of how intensively the equipment is used, and it would be influenced by bus travel speeds and different levels of service during peak and off-peak time periods. The direction of the indicator is known since a more uniform demand for service over the day would result in a higher number.

This indicator, however, tells nothing about the impact of the service on the community. Another indicator that might be used would measure the volume of pollutants removed (because of reduced auto driving) divided by bus vehicle miles. This would be more informative from a livability standpoint, because it relates to a quality-of-life outcome, but it would be difficult to make assumptions based on the measurement’s direction because pollutants from mobile source emissions are impacted by a host of interrelated factors.

Indicator interpretation. Livability indicators developed in one place and time might not be relevant in another place and time.

Data availability and reliability. Increasingly, due to scarcity in readily available and suitable public data, proprietary data on livability have emerged. These proprietary data, although useful, are costly, with questionable reliability and availability over time.

Politics of use. Because of the politically contentious nature of policy and planning, indicators can trigger livability exercises that could become excuses for taking no action.

Measuring Transit Availability and Accessibility

Availability is a measure of the supply of transit as provided by the agency. While there are different indicators for measuring availability, commonly used indicators include the frequency of service, hours of service, and the service coverage. These measures are aggregated into an index for transit availability, which is calculated as the percent of person-minutes served.

Accessibility is a key component of livability that explicitly or implicitly underlies many measures and analyses of livability. Accessibility is also closely intertwined with policies that intentionally or unintentionally influence livability. Many livability measures assume that the resources and opportunities at a place are perfectly available to individuals who are proximal to that location. Policies that attempt to influence livability also make this assumption. However, factors other than proximity can affect the ability of individuals to obtain resources and opportunities. This means that measures can overestimate livability, and the effectiveness of related policies, by masking individual variations in the benefits actually obtained from resources and opportunities.

Low-Emission Vehicles

Low-emission vehicles (LEVs) are a subset of the global motorized road transport fleet that produces comparatively fewer emissions than those produced by a conventional internal combustion engine (ICE) fueled by gasoline or diesel.

The reduction in emissions is achieved through the implementation of a range of technological improvements that increase the efficiency of the vehicle or through the utilization of alternative fuels, such as biofuels, gas—most commonly compressed natural gas (CNG) or liquefied natural gas (LNG)—electricity, and hydrogen. Any of these alternatives may also be used in combination with

conventional fuels. One example is the current hybrid-motor systems used in passenger automobiles, which use both battery technology and fossil-fuel-powered internal combustion. While the term *vehicle* could be wide-ranging, most of the policy focused in this area, as well as the technological developments made, have been in the passenger car and light-duty truck sectors.

Early measures to control vehicle emissions, such as the catalytic converter that became standardized in the mid-1970s in the United States, around the time of the introduction of the Corporate Average Fuel Economy (CAFE) regulations. They were subsequently introduced worldwide and have given way to more systemic vehicle improvements designed to reduce both emissions of air pollutants such as carbon monoxide, nitrogen oxides (NO_x), volatile organic compounds and atmospheric particulate matter. More recently, LEVs have been introduced to reduce the impact of greenhouse gas emissions, primarily carbon dioxide (CO₂).

The issues of pollution addressed by air quality standard legislation and climate change have some complementary solutions, but there are some measures, such as the promotion of diesel engines as a comparatively lower carbon fuel, that actually exacerbate air pollution and the associated health impacts because of the increased levels of NO_x emitted by diesel-fuel engines. Such trade-offs emphasize the need to move toward non-fossil-fuel-based technology but also expose the complexity inherent in such shifts.

The term *LEV* gained prominence after California introduced a LEV program in 1990 that mandated tailpipe emissions standards more stringent than those required by the federal government.

Several variations in terminology have emerged over the past 20 years to differentiate between particular vehicle types. As well as LEVs and zero-emission vehicles (ZEVs), terms that have entered the parlance of the auto manufacturing community include *transitional low-emission vehicles* (TLEV), *super-low-emission vehicle* (SLEV), *partial zero-emission vehicles* (PZEV), *ultra-low-emission vehicles* (ULEV), *super-ultra-low emission vehicles* (SULEV), and *advance-technology partial-zero-emission vehicles* (AT-PZEV). Most of the acronyms developed as California's legal response has progressed, although the utility of such an array of distinctions has been questioned.

Government and Industry Initiatives

Over the past two decades, government and industry initiatives have been developed across the world to promote the introduction of LEVs, with the United Kingdom government even establishing an Office of Low Emission Vehicles to manage the Department of Transport's work in this area.

Following the introduction of the CAFE standards in the United States in the mid-1970s, so-called voluntary agreements to increase the fuel efficiency of new vehicles were struck among members of major auto-manufacturing associations worldwide, including the European Automobile Manufacturers' Association, the Japan Automobile Manufacturers Association, and the Korea Automobile Manufacturers Association in the mid-1990s. The voluntary agreements were largely unsuccessful in delivering the scale of reduction of tailpipe emissions that were targeted by the companies, and in Europe, at least, manufacturers are now mandated to deliver reductions through the 2009 CO₂ regulations for cars.

Despite the failure to achieve the specific targets, numerous significant technological advances were made over the time of the agreements to improve the efficiency of conventionally fueled vehicles in the area of emissions. Such measures include light-weighting through manufacturing cars using lighter and more resilient materials; regenerative braking, where energy ordinarily lost in speed reduction can be stored and used to power the vehicle and save fuel; and through the use of low-rolling-resistance tires.

There have also been developments across the world to shift fleets away from oil toward less emission-intensive fuels. In the 1990s and early 2000s, much attention was given to the potential of bio-fuels (ethanol) and CNG as potential gasoline substitutes because they were relatively low-cost, and, in the case of biofuel, would require little modification to the current vehicle technologies. Research and pilot programs were initiated, but, for the most part, biofuels have not been widely adopted.

Obstacles to wide biofuel use in passenger vehicles include improvements in the efficiency of gasoline and diesel fuels, and increasing concern over the viability of large-scale biofuel production. The U.S. government's interest in biofuel, for example, fueled a major increase in farmers' growing corn, which then sparked fears that biofuel crops would have to compete with those for food production.

An engineer in a thermal cell research facility at the U.S. Department of Energy's Argonne National Laboratory attaches hoses to an automobile to measure tailpipe emissions in 2009.

Since the introduction of an ethanol fuel program some 40 years ago in Brazil, vehicles powered by ethanol from sugar cane have become so prevalent that the country no longer has any vehicles running on pure gasoline. The fleet runs on either pure ethanol or so-called flex-fuel, a gasoline/ethanol blend (primarily E20-25). Although CNG was seen to hold potential as an alternative fuel in the 1990s, the improvements to conventional-fueled vehicles were sufficient to close most of the gap between gasoline and diesel and CNG. However, CNG and LPG have carved out some niches, such as taxis and transit buses, because the cost of natural gas is much lower than the oil-based fuels.

Since the introduction of the Toyota Prius onto the global market in 2000 (following a successful introduction in Japan in 1997), hybrid electric vehicles that combine a battery engine with a conventional ICE powertrain have shifted the attention of car buyers and automakers toward electrification over the past five years. E-mobility is now being promoted by governments and car companies alike.

In California, regulators have mandated that automakers step up the percentage of ZEV vehicles

sold in California through 2017, when a minimum of 14 percent of passenger cars and light- and medium-duty vehicles must produce zero emissions. In Europe, significant research and development is now focused on delivering electric vehicles and the associated infrastructure for recharging them, although to date sales of the electric vehicles currently on the market have been limited. Obstacles to adoption include the fact that current electricity-generation technology is not low emission.

Conclusion

The concept of the LEV has been accepted over the last 20 years, and the market has been transformed with much more energy-efficient vehicles. However, cars on the whole in the United States are getting bigger, and light trucks are becoming the vehicle of choice for many households. Add to that the trend for people to drive more and further every year and the positive developments being produced by the auto manufacturers in fuel efficiency are being cancelled out. Therefore, the challenge in delivering cleaner air and addressing climate change continues to be immense at the same time that the landscape for policy promoting LEVs seems to be getting more, not less, complicated.

Maglev Systems

Maglev, an abbreviation for magnetic levitation, describes the old idea but relatively new technology of using magnets to move noncontacting vehicles at high speeds reaching 250 to 300 miles per hour or more while they are suspended, guided, and propelled above a guideway. Despite the fact that early U.S. patents for a linear motor propelled train were awarded in the United States in 1905, Maglev railroad systems operated only in China, Germany, and Japan in the first decade of the 21st century.

The three underlying principles of Maglev technology are levitation or suspension, propulsions and guidance. Deriving from its technological principles, a Maglev rail system has three components which are a large electrical power source, metal coils lining a guideway or track, and large guidance magnets attached to the underside of the train.

How Maglev Rail Systems Operate

Maglev trains float on a cushion of air. In a Maglev system, magnets are installed on a vehicle's undercarriage and on a guideway a short distance away. Maglev guideways are made of steel, concrete, or aluminum which can be T-shaped, U-shaped, Y-shaped or box-beam. The magnets allow the vehicle to levitate between .039 and .93 inches above the guideway and electric power is supplied to the coils within the guideway walls, creating a system of magnetic

fields that pull and push the vehicle along the guideway. The electric current in the coils in the guideway walls constantly alternates to change the polarity of the magnetized coils. This change in polarity causes the magnetic field in front of the vehicle to pull it forward, while the magnetic fields behind the vehicle give it more forward thrust. Existing Maglev technology focuses on Maglev trains that promise dramatic improvements in rail systems if countries have the resources and political will to install them. Developers predict that Maglev trains will eventually link cities as distant as 1,000 miles apart.

Maglev Trains Compared to Conventional Trains

Electric powered and noncontact, the Maglev system does not rely on the wheels, bearings, and axles of the conventional rail systems. Maglev trains do not have the kind of engine used to pull conventional train cars along steel tracks. Since they are noncontact, weather does not affect Maglev trains and snow, ice, severe cold, rain or high winds don't slow them down or stop their operation.

The Maglev air cushion eliminates friction and this lack of friction and the aerodynamic design of the Maglev trains allows them to reach ground transportation speeds of more than 310 miles per hour, or twice as fast as Amtrak's fastest commuter train. The trains move more smoothly and quietly than mass transit systems with wheels. Also, Maglev

The Shanghai Transrapid Maglev train in a station in 2008. The only commercialized Maglev line as of 2013, this train is able to traverse nearly 19 miles in only eight minutes.

train systems can accelerate and decelerate more quickly than wheeled systems. Instead of using fossil fuels, Maglev trains are powered by electricity, and there is no need for signaling systems or whistles or horns on Maglev trains, because all systems are computer-controlled. No human operator could move fast enough to slow down or stop these systems, but two microwave towers are in contact with the Maglev trains at all times.

Currently operating Maglev trains have demonstrated minimal maintenance requirements, and the maintenance they do need is based on the number of hours of operation rather than speed or distance traveled. Unlike traditional railways, Maglev trains are not subject to the wear and tear of miles of friction on mechanical systems and do not incur the commensurate maintenance costs. Cheaper running costs give Maglev rail an advantage over conventional rail, and Maglev also offers better reliability, availability, and sustainability. There is one technical issue

with Maglev that does not affect traditional trains. Magnet reliability is typically lessened at higher temperatures, but new alloys and manufacturing techniques have produced magnets that can maintain their levitational force at higher temperatures.

Maglev trains produce less noise than a conventional train at equivalent speeds. The major noise source for Maglev vehicles comes from displaced air. Studies have indicated that Maglev noise levels should be compared to road traffic and rated accordingly, while conventional trains are judged at a different noise level. From an environmental perspective, Maglev trains cause less pollution than trains powered by fossil fuels. They are also more efficient people movers than passenger airplanes, transporting as many as 12,000 passengers per hour in each direction.

A major drawback of Maglev train systems is that they are not compatible with conventional track systems, requiring new infrastructure for their entire route. However, advocates argue that Maglev's completely separate infrastructure more than pays for itself because of its all-weather operational reliability and insignificant maintenance costs.

Several countries, including the United Kingdom, Canada, China, Germany, and Japan, have sponsored research and development programs into Maglev technology over the past two decades. Germany and Japan have each invested over \$1 billion to develop and demonstrate Maglev technology.

Maglev Trains in Japan, China and Germany

Japan's sleek bullet train system gained international fame in the 1960s, and more than 50 years later, the country is pioneering Maglev trains. In November 2012, Central Japan Railway Company (JR Tokai) unveiled a magnetic levitation train that can travel over 310 miles per hour. New trains scheduled to go into use in 2027 will link Shinagawa Station in central Tokyo with Nagoya, traveling at about 311 miles per hour. The extended plan is to have new trains connect Tokyo to Osaka by 2045, and Japan is also exploring the option of exporting its train technology.

Shanghai, a booming metropolis in east China, features the Shanghai Maglev Train (SMT), the world's first and only commercialized Transrapid Maglev train line. It runs from Pudong International Airport to Longyang Road Station, located at the intersection of Longyang Road and Baiyang

Road in Puong New Area. The entire journey takes only eight minutes to cover 18.6 miles.

Siemens and ThyssenKrupp of Germany built the train set in 2000 at a cost of \$1.2 billion. Local Chinese companies built the guideway. The Shanghai Maglev Transportation Development Co., Ltd. operates the Maglev Line, as well as the Shanghai Maglev Transportation Science and Technology Museum.

Engineers in the German company Transrapid International developed an electromagnetic suspension (EMS) system, called Transrapid. Even though German inventors helped pioneer this technology, Maglev trains have had slow going in Germany. Germany has a well-developed network of conventional high-speed trains, but the only Transrapid line in the nation so far is an experimental stretch in the rural northwest.

In this system, the bottom of the train wraps around a steel guideway, and electromagnets attached to the undercarriage of the train are directed up toward the guideway. This levitates the train about one-third of an inch above the guideway, keeping it levitated even when the train is not moving. Guidance magnets embedded in the body of the train keep it stable during travel. The train can reach speeds of 300 miles per hour.

During trial runs, Transrapid 08 carried passengers along a 19.8-mile test track running from Lathen to Dorpen, often reaching speeds of 280 miles per hour. In September 2006, the Maglev collided with a maintenance vehicle on the tracks near Lathen, killing 23 people. In March 2008, the German government announced it was abandoning plans to build a high-speed Maglev link with Munich airport because of spiraling costs. However, the transportation minister said that Maglev research and development would continue in Germany, and the country would continue to export Maglev technology.

The United States and Maglev Technology

On February 14, 1905, the U.S. Patent office awarded inventor Alfred Zehden a patent for a linear-motor-propelled train, followed by a second patent on August 21, 1907. G.R. Polgreen described an early modern type of Maglev train and was awarded his patent in 1959, as were Robert Goddard and Emile Bachelet. In 1968, James R. Powell and Gordon T. Danby were granted a patent for their design for a magnetic levitation train.

Under the High Speed Ground Transportation Act of 1965, the Federal Railroad Administration (FRA) funded extensive research into numerous forms of high-speed ground transportation through the early 1970s. In 1971, the FRA awarded contracts to the Ford Motor Company and the Stanford Research Institute to develop Electromagnetic and Electrodynamic systems, and these contracts produced the linear electric motor that is used by current Maglev prototypes. Federal funding for high-speed Maglev research in the United States ended in 1975, but research into low-speed Maglev continued until 1986.

Despite setbacks, advocates in and out of government continue to champion Maglev systems, which they say would provide transportation alternatives, in particular, for time-sensitive trips of 100 to 600 miles. In addition, Maglev systems would reduce air and highway congestion, air pollution, and energy use, and facilitate long-haul service at crowded airports.

In 1990, the National Maglev Initiative (NMI), a cooperative effort of government agencies, was established, including the FRA, the U.S. Army Corps of Engineers, and the Department of Energy. The NMI had the task of evaluating the potential for Maglev to improve intercity transportation, and developing guidelines to determine the role of the federal government in advancing this technology. The NMI identified several corridors extending hundreds of miles across the country that would benefit from Maglev trains.

Congress subsequently passed the Intermodal Surface Transportation Efficiency Act of 1991 (ISTEA), adding an appropriation of \$26.2 million to identify Maglev system concepts to be used in the United States, as well as to assess the technical and economic feasibility of these systems. Studies were also ordered to determine the role of Maglev in improving intercity transportation. Congress appropriated an additional \$9.8 million to complete the NMI studies. Since the 1990s, however, studies and funding that would advance Maglev technology have largely stagnated.

Marine Transportation System

The U.S. Marine Transportation System (MTS), a network of waterways, ports, and interlocking land connections, is an initiative of the Maritime Administration, the Coast Guard, and 10 other federal agencies. These federal agencies, in partnership with nonfederal agencies, work to ensure a safe, environmentally sound, world-class Marine Transportation System. The MTS comprises 25,000 miles of navigable channels, the Great Lakes, the St. Lawrence Seaway, 238 locks, more than 3,700 marine terminals, and recreational marinas. It also includes 174,000 miles of rail and more than 45,000 miles of interstate

highway. More than 1,400 connections have been designated intermodal, which means that people or cargo must change transportation modes at a place where two or more forms of transport meet.

The U.S. Department of Transportation's Bureau of Transportation Statistics has estimated that the total value of marine freight will increase by 43 percent domestically and 67 percent internationally between 2010 and 2020. Ferry passenger transportation is growing rapidly because of traffic congestion on land, and use of the MTS by commercial fishing entities and the military is also expected to grow. Maritime transport must also be safely handled and balanced with environmental values to ensure that freight and people move quickly and efficiently to, from, and on American waterways. The MTS provides vital national security assistance by transporting and sustaining the American military. More than 90 percent of all equipment and supplies for the 1990 to 1991 Gulf War were shipped from strategic ports on inland and coastal waterways.

The MTS serves 78 million American recreational boaters who boat, fish, sail, canoe, and kayak, and its records illustrate the tremendous monetary boost that recreational boating gives to the American economy. The U.S. Coast Guard, as part of the MTS, takes a proactive approach in identifying potential causes of recreational boating accidents and deaths and setting attainable goals to reduce both. The MTS also supports the 110,000 commercial fishing and recreational vessels that together contribute \$111 billion to state economies. The more than 5 million American cruise ship passengers a year also come under the umbrella of the MTS.

The Marine Transportation System and the Environment

Marine Transportation System members strive to provide environmentally responsible modes of transportation. According to the Maritime Association, ships and barges have the fewest accidental spills or collisions of all forms of maritime transportation. Members of the MTS advocate environmental responsibility, including cleaning up polluted waterways, refraining from overfishing, and banning operations like dredging or trawling that damage the environment.

The U.S. Coast Guard and the National Oceanic and Atmospheric Administration (NOAA) are just two of the MTS agencies that work together to

The U.S. Coast Guard's Legend Class National Security Cutter Bertholf visits the San Diego Naval Base, November 12, 2008. It is estimated that the total value of marine freight will increase by 43 percent domestically and 67 percent internationally from 2010 to 2020. The Coast Guard facilitates this trade through its maritime security efforts and environmental activities, including monitoring oil, air, and plastics pollution; aquatic nuisance species transported by vessels; and related international agreements.

manage environmental disasters like oil spills and hurricanes. Both agencies assisted in the Deepwater Horizon oil spill cleanup in the Gulf Coast and along all affected shorelines.

Coast Guard men and women rescued 3,584 people and transported them to safety during Hurricane Katrina in 2005. In the 2011 Midwest floods, Coast Guard personnel deployed to support federal, state, and local agencies throughout the Midwest and southern United States to rescue people from the record floodwaters along the entire Mississippi River system. In Louisiana a Coast Guard unit, the Marine Safety Unit Baton Rouge, daily checked the Mississippi River for damage and assisted local people and businesses.

The Maritime Administration, part of the U.S. Department of Transportation, has played an important role in dealing with problems stemming from foreign aquatic species entering American waters through ballast water, including zebra mussels, rapa whelk, spotted jellyfish, and Asian carp. The Maritime Administration is cooperating with

other MTS agencies to monitor ballast systems without disrupting the flow of vessel transportation.

For several years, the Maritime Administration has partnered with NOAA and the U.S. Fish and Wildlife Service (FWS) to promote the development and demonstration of technologies to treat ballast water. Costs and difficulty of installing a full-scale treatment system for ship ballast water are drawbacks, but the Maritime Administration has offered its ships for limited shipboard tests.

National Security Assistance and Terrorist Education

Since the September 11, 2001, terrorist attacks on the United States, maritime security efforts have mainly focused on commercial vessels, cargoes, and crew, paying only limited attention to safety and basic law enforcement rules for smaller vessels. Gradually, though, MTS members have realized that smaller vessels are especially likely to be used for illegal immigration and by terrorists to smuggle weapons of mass destruction, narcotics, and other

contraband. Terrorists overseas have successfully used small boats to deliver waterborne improvised explosive devices.

Maritime authorities face the challenge of separating the thousands of legitimate mariners from the few who conduct illegal activities. The challenge is daunting because it involves nearly 13 million registered U.S. vessels, 82,000 fishing vessels, and 100,000 commercial small vessels. Many of these boats share waterways, ports, and bridges with commercial and military traffic, and they can easily access high-risk military installations such as petrochemical plants. The Homeland Security Act of 2002 divided the Coast Guard's mission between homeland security and non-homeland security. The Homeland Security Act identified ports, waterways, and coastal security as the first homeland security mission, and the commandant of the Coast Guard designated coastal security as the Coast Guard's primary focus alongside search and rescue. The Coast Guard's mission includes the protection of the U.S. maritime domain, the U.S. MTS, and those who live, work, and enjoy recreation near them. The Coast Guard also strives to prevent and disrupt terrorist attacks, sabotage, espionage, or subversive acts, and to respond to and recover from the terrorist attacks that do occur.

The Coast Guard also supports America's Waterway Watch, a public outreach program that encourages people to report suspicious activity to the Coast Guard or to other law enforcement agencies. Towboat operators, recreational boaters, marina managers, and other people who live, work, or play around America's waterways are in a unique position to keep waterways safe by keeping their eyes open.

The Maritime Security Response Team is a Coast Guard team highly trained in counterterrorism skills and tactics; its members are trained to be first responders to potential terrorist situations. The Coast Guard team tightens security measures against terrorists, conducts port-level counterterrorism exercises, and teaches Coast Guard counterterrorism procedures.

Coast Guard cutters, boats, helicopters, and shoreside patrols are part of maritime antiterrorism activities, and many Coast Guard activities support the Department of Homeland Security's Small Vessel Security Strategy. Twelve marine safety and security teams patrol security zones, conduct port state control boards, protect military installations,

ensure maritime security during major marine events, augment shoreside security at waterfront facilities, search for weapons of mass destruction, and participate in port-level antiterrorism exercises in their home and other ports.

In 2002, Congress passed the Maritime Transportation Security Act, citing the exposed and open nature of ports and their vulnerability to terrorist acts, which could cause a large loss of life and economic disruption. The act identified a special security risk to the cruise ship industry. The legislation called for improved inspection of containerized cargo, implementation of biometric identification procedures for individuals who have access to port facilities, and the securing of entry points and other areas of port vulnerability.

Coordinating maritime initiatives and policies as part of a larger system creates a more efficient MTS and overlapping domestic and international safety nets, layers of security, and effective vigilance, making it harder for terrorists to succeed.

The Coast Guard and Maritime Transportation Act of 2012

On December 20, 2012, President Barack Obama signed the Coast Guard and Maritime Transportation Act of 2012, creating new authority, responsibilities, and opportunities for the MTS and creating the U.S. Committee on the Marine Transportation System (CMTS). The purpose of the CMTS is to assess the adequacy of the MTS, promote its integration into the overall marine environment, and coordinate and make recommendations regarding federal policies that affect the MTS. The act confirms the membership in the Marine Transportation System of the Coast Guard and the CMTS and allows them to share resources and consult with other MTS members. The CMTS is required to report on the implementation of actions it has recommended in the *National Strategy for the Marine Transportation System: A Framework for Action* and to provide an assessment of the condition of the MTS.

Critical Issues Facing the Marine Transportation System

Even though the MTS is an efficiently operating network, it faces many future challenges. The number of recreational boaters is expected to grow by more than 130 million annually in the next 20 years. High-speed ferry transportation is growing rapidly

because of land transport congestion, and commercial fishing is expected to increase. Military reliance on the MTS is also expected to grow substantially.

American companies are facing a more competitive environment, and they must restructure themselves to serve larger and more demanding markets. Ports and other MTS operators also must meet more stringent requirements to successfully compete for American business. MTS ports and facilities must function more swiftly and less expensively while moving goods reliably and securely. Transportation providers must be ready to forge new business alliances and deploy new technologies and equipment to reduce the cost of moving goods and to meet the requirements of shippers. Future changes include constructing larger and faster vessels capable of carrying more than 6,000 20-foot containers, double-stack trains for transporting shipments over land, and advanced tracking systems.

The physical infrastructure and information systems that support MTS must be improved to adapt to changing needs. Infrastructure issues include dredging and marking harbor channels connecting U.S. ports to the world. Dredging requirements can be expected to grow because deeper waterways will be required for larger vessels. Nearly half of America's inland waterway locks and dams are at least 50 years old, and many locks are undersized for modern commercial barge operations. Modernizing locks and dams to regulate water flow and facilitate commerce is a necessary expense. Improving marine terminal capacity and access to rails, roads, and pipelines is also necessary to efficiently move goods across geographical areas.

Updating computer communications and navigational technologies to increase the productivity, safety, and security of the MTS is a necessary reform measure. Installing technologies such as intelligent transportation systems, differential global positioning systems, vessel traffic services, physical oceanographic real-time systems, and electronic navigational charts will bring systems into the 21st century.

The Marine Transportation System 2020

The vision of the private, state, local, and national agencies comprising the U.S. MTS is to make it the world's most technologically advanced, safe, secure, efficient, effective, accessible, globally competitive, dynamic, and environmentally responsible maritime system for moving goods and people. According

to people involved in federal legislation and state, local, and private MTS operations, aggressive, cost-effective technology development and deployment to ensure long-term competitiveness and continued cooperation and coordination are essential in achieving the MTS vision. The guiding principles essential to making this vision a reality include environmental, security, and commercial components.

Coastal water, estuaries, inland rivers, wetlands, and habitats are included in the MTS. Its users, from recreational boaters to commercial vessels and waterfront terminals, must work to protect and sustain the environment. Marine operations, maintenance, and investments should integrate environmental protection. Environmental quality is crucial for sustaining coastal and marine ecosystems, commercial and recreational fisheries, and the economic vitality of the MTS. Decision making and planning should acknowledge the interdependency of the MTS and the environment.

The MTS faces rising international organized crime and a growing number of rogue states and terrorists, all seeking to exploit vulnerabilities in the system. New funding methods for the MTS need to be explored and implemented. Federal funding, including user fees and private investment alternatives, should be investigated and coordinated public funding processes put in place.

Coordination at the national level consists of a new federal Interagency Committee for the Marine Transportation System (created through the expansion of the Interagency Committee for Waterways Management) and a Marine Transportation Agency National Advisory Council. The Interagency Committee for the MTS is the national coordinating body where federal agencies responsible for one or more aspects of the MTS discuss strategies to minimize duplicate efforts and coordinate overlapping functions. The Marine Transportation System National Advisory Council is composed of senior-level representatives from nonfederal organizations. Additional key elements of the MTS coordination framework include local and regional committees. People, workforce, passengers, and legislators, as well as state, regional, and local officials, are critical to the successful operation of the MTS and essential to the fulfillment of its vision for the future.

Maritime Administration

The U.S. Maritime Administration (MARAD) is an agency of the U.S. Department of Transportation. Its mission is to improve and strengthen the U.S. marine transportation system and enable it to meet the country's environmental and security needs. The official who runs MARAD, known as the maritime administrator, works for the secretary of transportation. The maritime administrator is also

the chairperson of the Maritime Subsidy Board, the commandant of the U.S. Maritime Service, and director of the National Shipping Authority.

Established in 1950, MARAD deals with all aspects of waterborne transportation, promoting the use of waterborne transportation and ensuring its seamless integration with other segments of the transportation system. Responsible for the U.S. Maritime Service and the U.S. Merchant Marine, the agency works to maintain shipbuilding and repair services, ports, intermodal water and land transportation systems, and reserve ships for national emergencies. It provides services and sets the routes that are needed for foreign commerce, including the requirements of ships serving the routes. MARAD also conducts research and development activities in the maritime field and regulates the transfer of U.S.-documented vessels to foreign registries.

History of the U.S. Maritime Administration

MARAD traces its roots to the Shipping Act of 1916, which established the U.S. Shipping Board; this was the first federal agency with the mission of promoting maritime interests and regulating U.S. commercial shipping.

The Shipping Board created a naval auxiliary, naval reserve, and merchant marine. The Shipping Board also created the Emergency Fleet Corporation (EFC) just days after the United States officially entered World War I, to oversee ship construction and to acquire, manage, and operate ships. After the war ended, the Shipping Board continued to build ships until 1921, having produced nearly 2,300 ships. This surplus of vessels, in turn, created an industry depression. In 1928, the EFC was renamed the Merchant Fleet Corporation (MFC), and in 1930, the Department of Commerce absorbed the MFC and the Shipping Board and reinvented the two agencies as the U.S. Shipping Board Bureau.

The Merchant Marine Act of 1936 established the U.S. Maritime Commission, which assumed the duties, functions, and property of the Shipping Board Bureau, and was assigned the task of advancing and maintaining a strong merchant marine to support U.S. commerce and defense. The commission regulated ocean commerce, and designed and constructed 500 merchant ships over a 10-year period. President Franklin D. Roosevelt appointed

Joseph P. Kennedy Sr., father of future president John F. Kennedy, as the commission's first chairman.

When war broke out again in 1941, the construction program was in full swing, and the Maritime Commission's peacetime purpose changed, just as the Shipping Board's had in 1917. In 1942, President Roosevelt issued Executive Order 9054, separating the Maritime Commission into two agencies: the Commission to Design and Construct Ships and the War Shipping Administration (WSA), which would procure and operate them. Working closely together between 1941 and 1946, the Maritime Commission and WSA built nearly 6,000 merchant vessels and naval auxiliaries. The WSA was also managing the operations, repair, and maintenance of thousands of ships. In 1946, the government dissolved the WSA and transferred its operations back to the Maritime Commission. Thousands of ships were sold or scrapped under the Merchant Ship Sales Act, but the Maritime Commission retained a group of reserve ships called the National Defense Reserve Fleet.

In 1950, following President Harry S. Truman's recommendations in Reorganization Plan No. 21, Congress dissolved the U.S. Maritime Commission, dividing its duties between the newly created Maritime Administration and the Federal Maritime Board (FMB) and assigning both organizations to the U.S. Department of Commerce. In 1961, as part of Reorganization Plan No. 7, the FMB became an independent regulatory agency and was renamed the Federal Maritime Commission. The subsidy function of FMB returned to MARAD as the Maritime Subsidy Board, reporting independently to the MARAD Administrator. The 1961 reforms are the foundation of MARAD's 21st century organizational structure. In 1981, MARAD was transferred to the Department of Transportation as part of a consolidation of all federal transportation programs into one cabinet-level department.

The U.S. Merchant Marine

Established in 1938 under the provisions of the Merchant Marine Act of 1936, the U.S. Maritime Service (USMS) was given responsibility for training people to become officers and crew members on ships of the U.S. Merchant Marine. This service is now under the authority of the MARAD, with the Maritime Administrator acting as the commandant. This person also serves as the director of the

National Shipping Authority and the chairperson of the Maritime Subsidy Board. The commissioned officers of the USMS serve as administrators and instructors at the U.S. Merchant Marine Academy and the maritime academies.

Both the U.S. government and the private sector have operated ships in the merchant marine fleet, which comprises all vessels engaging in commerce or transportation of goods and services in the country's navigable waters. The merchant marine transports cargo and passengers during peace time, and the U.S. Coast Guard, the Department of Transportation and the Maritime Administration regulate the ships. People who serve in the merchant marine are called mariners, sailors, commercial sailors, or seafarers.

The merchant marine also functions as an auxiliary in war or national emergency by transporting goods or materials for the armed forces, serving in every U.S. war since 1775. The merchant marine played a pivotal noncombat role in World War II, delivering troops and supplies for the military. During World War II, the federal government controlled the cargo and destinations of merchant ships and trained people to operate the ships through the USMS.

In the 21st century, MARAD is still in charge of maintaining a strong merchant marine. To train and educate those who are operating the fleet, MARAD operates the U.S. Merchant Marine Academy at Kings Point, New York, and provides funding and maintains training ships for six state maritime academies, including the State University of New York Maritime College in the Bronx, New York; Massachusetts Maritime Academy in Buzzards Bay, Massachusetts; California Maritime Academy in Vallejo, California; Maine Maritime Academy in Castine, Maine; Texas Maritime Academy in Galveston, Texas; and the Great Lakes Maritime Academy in Traverse City, Michigan. MARAD also offer maritime training, degrees, and certification.

The National Defense Reserve Fleet

Established under Section 11 of the Merchant Ship Sales Act of 1946, the National Defense Reserve Fleet (NDRF) maintains ships that can be called into service for 20 to 120 days for national defense and national emergencies. MARAD manages the NDRF, which is made up of mothballed ships,

mostly merchant ships. The NDRF also logistically supports the military when necessary.

Vessels that are deemed valuable for military or logistical reasons are placed in a preservation program designed to keep them in the same condition they were in when they entered the fleet. Their internal spaces are dehumidified to slow metal corrosion and inhibit mold growth and mildew. Workers send electric current to exterior underwater portions of the hull, which creates an electric field, suppressing corrosion and preserving the hull's surface. Workers generally do not paint the outside of the ship or perform cosmetic alterations, because their focus is maintaining operation of the vessels, not aesthetics.

NDRF vessels are moored at fleet sites on the James River in Virginia and in Beaumont, Texas. Other vessels are gathered at Suisun Bay, California. At its peak in 1950, the NDRF was in charge of 2,277 mothballed ships, but by 2000, only 274 were in reserve. In July 2007, the 230 ships in the reserve fleet were mostly dry cargo ships, along with some tankers, military auxiliaries, and other kinds of vessels. The Suisun Bay location contained 324 ships in 1959. By 1999, the number had fallen to about 250, but the vessels had created an accumulated pollutant problem. Paint containing lead, copper, zinc, barium, and other toxins continuously flaked off of the hulls and superstructures of many of the ships. By June 2007, the ships had shed about 21 tons of toxic paint debris, which settled in the sediment of Suisun Bay, MARAD personnel estimated. MARAD identified 52 ships as problematic and scheduled them to be removed and recycled by September 2017.

Through special legislation, the NDRF program has the ability to lend or give historic artifacts or transfer entire ships to maritime heritage organizations.

Maritime Industry

Understanding the modern maritime industry necessarily begins with coming to terms with its dimensions. It is a cliché factoid of middle school social studies that 70 percent of the world is covered with water, oceans, inland water systems, rivers, and lakes. The fact that 80 percent of that global water system is navigable creates a maritime industry that, despite the relatively slow speeds of ships, is the largest and most efficient transportation system humanity has ever constructed. Few people not directly involved with maritime transportation grasp the vastness of the world’s waterways—for example, a container vessel—a massive (most more than 20 stories high) but relatively common ship used to transport goods, foodstuffs, and minerals in bulky truck-sized containers—can travel the equivalent of a trip to the moon and halfway back in a normal year.

More than planes or trains or trucking, the maritime industry provides critical connections between nations, between businesses, and between production facilities and consumer markets. And given the industry’s use of the natural energy and sheer power of waterways and the intricate connections of water systems that provide access to virtually any market anywhere, the maritime industry is the cheapest mode of transportation available for both goods and people. What is sacrificed in speed—the average cargo-carrying vessel today travels just under 30 knots per hour, or about 45

miles per hour—is gained in the accessibility and reach of the world’s waterways.

History

In many ways, more than 3,000 years ago, the maritime industry provided a kind of template for the international networking constructed over the last generation through the reach of the Internet. Nearly four millennia before the advent of modern transportation systems—the railroad, the internal combustion engines, and the airplane—began to reconfigure the world into a global market, the Egyptians first tested the viability of a maritime economy, and subsequently, virtually every significant civilization in antiquity (the Greeks, the Romans, the Phoenicians, the Japanese, the Chinese) relied on sailing to provide the most economically sound system of transporting goods and people, relying on shipping not only to secure global markets but also to establish a military presence in far-flung outposts.

In post-Renaissance Europe, the storied rise of the great sea powers and the nearly two centuries of global exploration, militarization, and colonization—most notably the vast navies of Spain, Portugal, England, France, and the Netherlands—redefined the importance of the maritime industry. With the advent of steam-powered engines and the emergence in the mid-19th century of a global maritime industry that did not rely on the vagaries of wind to power its ships, the maritime industry established itself as the most dominant transportation system ever conceived.

Today’s Maritime Industry

But if it is the oldest transportation system, shipping is as well central to the 21st century global economy. Today’s maritime industry very much maintains a global presence; conservative estimates suggest that upwards of 90 percent of consumer goods worldwide depend either in their production or in their distribution on transportation through shipping.

Given that the maritime industry must deal with multiple governments with a variety of transportation codes, tax systems, regulatory agencies and bureaucratic protocols, international shipping conglomerates are notoriously secretive about their operations, the ownership of their vessels, the size of the crews they staff, the number of licensed ships in their fleet, and even the cargo they carry.

Although exact numbers are difficult to come by, *Clarkson's Shipping Intelligence Weekly*, the bible of the industry, places the number of cargo-carrying ships globally at just under 60,000. Factoring in other types of smaller ships (harbor patrols, cruise liners, passenger ships, small merchant vessels, pleasure crafts), the number is closer to 90,000.

Data on crew sizes are difficult to establish as well. Although officers and administrative staffs are among the most highly educated and best paid transportation workers in the world, the vast majority of crew members are the barely educated, undocumented (and underpaid) poor from a variety of Third World countries who must work in difficult and dangerous conditions and who are routinely exposed to illnesses given that the crews work and live in the same environment often for months at a time in confined spaces with shared water and waste systems, inadequate ventilation, minimum attention to moderating temperatures, and with access to basic medical services at best.

Because so much space in ocean-going vessels must be given over to accommodate ever-increasing metric tons of cargo, little thought is given to providing habitable space for the crews. International health organizations routinely rate ships among the most hazardous work sites; workers are prone not only to accidents and falls but also to injuries from electrical shock, chemical exposure, excessive noise, and burns, as well as the physical, emotional, and psychological stress inevitable during prolonged voyages in open water away from family.

Related Businesses

Perhaps more difficult to measure than the reach of the shipping industry is the variety of services and businesses, both at sea and on shore, that come under the heading of the maritime industry. Most obviously, the industry includes those businesses involved with the design and production and acquisition of the ships themselves as well as the crews that maintain their service (and travel with the vessels) and the land-based industries that provide component parts for the ships. In addition, there is a vast superstructure of global transportation companies that monitor the shipping lanes, track and direct traffic and weather patterns, and maintain safe routes in the ever-changing environment of the sea.

There are international legal services specializing in maritime law that protect both the shipping interests as well as companies who rely on shipping and the passengers who use the services. Factor in the banks, insurance companies, and the network of services provided routinely at ports and harbors and terminals from traffic management to customs agencies to loading crews and maintenance staffs, and the dimensions of the maritime industry begin to emerge. Of course, this does not factor in the vast military dimension of the maritime industry (data on that is of course difficult to come by) or the large armada of research vessels that daily are gathering volumes of scientific data on the conditions of the world's water ways, or the small-vessel industries such as fishing and public transportation (water taxis, ferries, and bus-boats), or the hundreds of both floating and permanent drilling rigs and the network of services that maintains them.

Given the vast reach of the maritime industry, measuring its actual economic dimension is at best problematic. Entire national economies such as Denmark and Japan and Australia as well as a host of archipelago nations such as the Philippines, Indonesia, the United Kingdom, and Taiwan, almost entirely rely on their maritime industry; more than two million jobs are tied to the maritime industry in Europe alone. The production value of China's maritime industry, itself considered in its infancy, accounted for more than \$800 billion in 2012: nearly 10 percent of that country's entire economy.

Types of Vessels

If the reach, economic impact, and scale of the maritime industry are difficult to measure with any exactness, the types of vessels considered part of the maritime industry's profile are a bit clearer. In general, 10 types of vessels make up the maritime industry. Bulk carriers are the most familiar large boats, with cavernous watertight hulls that are, in turn, filled with coal, grains, or oil. Containers, as their name suggest, transport mineral resources, foodstuffs, and other goods in large containers about half a football field long. Refrigerator ships transport perishable foodstuffs, dairy products, and fruits and vegetables. Vehicle ships, also known as roll-ons and roll-offs, transport cars, trucks, airplane parts, and even train cars. Oil tankers are responsible for transporting not only fossil fuels

but also chemicals and natural gas in pressurized containers. On a smaller scale, easily recognized flat-top barges transport goods on interior lakes and river systems. Tugboats maintain traffic control in busy international harbors by pushing and redirecting large carriers to permit maximum efficiency for incoming and outgoing ships. There are numerous small-business vessels, most prominently fishing boats, that, despite their relatively small size, account for significant percentages of local economies. At the far end of the scale are the passenger vessels, both the transportation vessels associated with public transportation needs in cities and island nations and the burgeoning international tourist cruise industry.

Challenges

Although transportation systems analysts believe that the maritime industry is very much a part of the 21st-century global market—like the Internet a macroeconomic environment that will be instrumental in providing stable growth for national economies—the industry faces enormous challenges in the new century, most prominently in response to rapidly dwindling fossil fuel supplies and the effects of global warming and climate change that have in the last generation grown to alarming dimensions. In response, transportation systems analysts project that the maritime industry, in addition to investing in the construction of more vessels, must address the design of the ships as well, particularly large ocean-going transport vessels. Making these critical ships both larger and lighter would enhance the delivery potential of the maritime industry; nautical engineers have determined that doubling the size of a ship triples its cargo-carrying capacity.

Ships within the next generation must also begin to rely less on fossil fuels; the most attractive alternative is nuclear powered engines, although their cost is currently prohibitive and there are enormous safety concerns. Given that fossil fuel dependency is the most likely scenario at least for the next half century, advocates of energy use point out that cutting-edge engine technology needs to make the current fleet of transport ships quicker, their propulsion more engaged. In addition, shipping analysts vigorously promote manning major ports of call with additional work crews to cut downtime for global carriers—container ships, which provide most of the shipping industry work,

can spend more than half a year in port undergoing maintenance and being loaded or unloaded.

Proponents of the maritime industry offer far broader options than ship design. Construction and upkeep of canals, critical in threading waterways and providing more efficient transport options, lag far behind needs; often canals suffer infrastructure fatigue, surviving on basic maintenance because of government interference, downsized economies, or labor uncertainties. Major harbors will need to be re-examined and in many cases dredged to permit deeper waters in an era of shrinking sea levels.

In the first decade of the new century, for instance, states along the Great Lakes, particularly Michigan and Minnesota, began an aggressive (and expensive) campaign to dredge major ports and canals to improve navigability. More potentially impactful than increasing ship size and speed, however, are long-term plans to convert close to 40 percent of individual ship operations to automation by 2030. Automation has already aggressively improved harbor service, providing efficient around-the-clock maintenance of busy ports and better regulating the loading and unloading of boats. Transportation specialists see as inevitable, however, that automation on board ship will eventually allow shipping companies to downsize crews, converting navigation systems, security systems, and maintenance systems to permit companies to cut more than 25 percent of the current workforce.

Conclusion

Although the realities of the world's maritime industry lack the romantic aura of classic seafaring clichés, and despite the evident advantages in the speed of other transportation systems, transportation systems analysts perceive the global shipping industry, because it is relatively cheap and because it is comparatively environmentally friendly, as vital in the new century's evolution into a global economy.

Metropolitan Planning Organizations

Metropolitan planning organizations (MPOs) were established as a part of the Federal Aid Highway Act of 1962. They play a significant role in transportation planning and regional governance across multijurisdictional metropolitan areas with populations of 50,000 or more. The roughly 400 MPOs in operation vary considerably in organizational structure, including size and composition of membership, planning boundaries, level of technical expertise, funding levels, programs and responsibilities, and standing within their regional structure.

This variety is by design, as federal legislation leaves much flexibility. Latitude is given for MPO structures to facilitate the most efficient and representative form of metropolitan transportation planning, given the inevitably unique features of geographic and institutional context. Diversity of form and function contributes to planning effectiveness, as MPOs serve a range of metropolitan areas, from newly designated urbanized areas with a few jurisdictions in their metro area to large multijurisdictional regions with many independent municipalities.

MPOs increasingly share regional planning responsibilities with the states. This shift in planning roles in recent decades was intensified by the Intermodal Surface Transportation Efficiency Act (ISTEA) of 1991. However, many challenges still persist, especially as they relate to regional and intergovernmental cooperation.

Most MPOs are housed in and staffed by one of their member jurisdictions. Otherwise, they may be located within a regional or state agency. Some are part of regional planning councils or regional councils of governments, but others function as independent, free-standing organizations. At a minimum, the MPO is required to have a governing board, a technical committee, and a citizens' advisory committee, but some have additional committees, such as freight or transit advisory committees.

The MPO governing board adopts and endorses regional transportation plans, approves budgets and agreements, adopts rules, and oversees MPO operations. In practice, a typical MPO board is geography-based, comprising representatives of localities in the region. These board members are mostly appointed and consequently may not equally represent all interests in the region. The citizen advisory committee brings citizen participation to transportation planning.

The primary role of an MPO is to ensure that transportation decision making includes consideration of all the transportation needs of the metropolitan area, along with consideration of their consequences for land use, housing patterns, and economic development. Charged with addressing the broad spectrum of stakeholder needs, the MPO works collaboratively with local communities, governments, and transportation agencies to facilitate the meaningful involvement of the public.

To fulfill their responsibilities, MPOs assume a leadership role in developing the short-term Transportation Improvement Program (TIP) and Long-Range Regional Transportation Plan (LR RTP). The latter allocates federal funds for transportation projects within the region for 20 years or more. Among its obligations, the MPO is required to obtain citizen participation to develop, maintain, and propose the TIP and LR RTP. By law, these plans must be fiscally constrained and must link projects to revenue sources. The MPO presents these plans to the state, and then negotiates with state officials the ultimate project list for the region.

As a result of this partnership approach, the state is compelled to adopt some, but not necessarily all, of the planning suggestions from once-weak regional or local entities or jeopardize federal funding. In this way, the federal government places authority directly in the hands of the MPO. The MPO must find a balance between its relationship with the state and multiple relationships in its regional network of localities and community stakeholders.

MPOs in Transportation Planning

The Federal Aid Highway Act of 1962 mandated that states create MPOs and grant them responsibility for comprehensive, cooperative, and continuing (“3Cs”) planning. However, the actual role played by MPOs in transportation planning was somewhat limited. It was not until the passage of the Intermodal Surface Transportation Efficiency Act (ISTEA) of 1991 that MPOs became securely integrated into transportation planning.

ISTEA had several provisions to strengthen the role and authority of MPOs in coordinating regional transportation planning. Through ISTEA, MPOs were, in effect, recreated as umbrella organizations to coordinate transportation programs within a multijurisdictional region, engage citizens, and facilitate discussion among stakeholders as part of a bottom-up transportation planning process. The basic framework for metropolitan decision making, as established by ISTEA, gives the MPO lead responsibility but mandates partnerships with the states and other stakeholders.

By expanding the role of MPOs, the federal government decreased the decision-making power of the state and empowered localities to operate through the MPO to devise a cohesive transportation plan for the region. Successor federal legislations (such as TEA-21, SAFETEA-LU, and MAP-21) continued the bottom-up model of regional transportation planning, thereby maintaining the significant role of MPOs.

MPO Relations With State Governments

The state, regardless of its traditional power over localities, must cooperate with the MPO in transportation planning. Yet, the MPO must cooperate with the state. Even though the MPO is empowered with more authority in transportation planning, it is still dependent on its relationship and coordination with the state. The state ultimately has more

overall power because it can easily work to veto a regional plan.

When ISTEA was passed, state transportation agencies were generally not in favor of bottom-up planning and MPO involvement, and they were displeased at the states’ diminished power in transportation decision making. As a result, MPOs sometimes had difficulty obtaining necessary information from the state in forming their plans. Budget information has been particularly difficult to obtain from states, making it challenging for the MPOs to effectively plan. Although the states comply when asked to do so, they are not always forthcoming with the necessary information, which increases the burden on the MPO. Regardless of the power given to the MPO under federal law in the planning process, all funds funnel through the states from the federal government to the localities. Power ultimately resides within the purse strings, where MPOs and state transportation agencies are hardly equal, but by law, the role of the MPO cannot be eliminated or significantly minimized.

Inter-Jurisdictional Cooperation and Planning

Under ISTEA, the MPO must collaborate with other planning entities regarding land-use planning, air quality and other environmental issues, and economic development. Yet, the MPO only has legal authority to provide transportation planning and related land-use planning.

Within metropolitan areas, individual jurisdictions can have differing, sometimes competing, interests. For example, cities reliant on mass transit tend to emphasize expansion of transit and the demands of the transit sector. The suburbs are more likely to seek more lane miles of highway. Too often, representatives from central cities and outer suburbs fail to come together for the good of the region but pursue instead the best deal for the locality they represent.

MPOs tend to emphasize automobile traffic, and very few MPOs include representatives from other modes, such as freight, airports, and rail. As a result, MPO boards tend to under-represent central cities and inner suburbs, and over-represent suburban interests. This can also produce under-representation of certain racial and ethnic groups, and such representational issues can significantly undercut the authority of MPOs.

Successful MPOs

Research has identified several characteristics of effective MPOs, including strong leadership, staff competence, credibility, quality public involvement, development of a regional ethos, streamlined and efficient processes, cooperative relationships with state transportation agencies, and accountability to members. Three of these characteristics are most crucial: highly competent MPO staff, high credibility, and strong leadership.

Competent staff is needed to ensure effective transportation planning, which is both complex and highly technical. To balance many competing demands during transportation planning and respond effectively to a range of interests, strong, dynamic leadership is essential. When leaders and staff are not held in high regard, they lose their credibility, and stakeholders lose trust in the planning process. The state will then be less likely to take the MPO's recommendations seriously. However, no matter how well-organized, competently staffed, and effectively run, all MPOs face the daunting challenges that are part and parcel of operating within a wide regional and intergovernmental context. With few exceptions, multijurisdictional transportation plans are a product of lengthy discussion and negotiation.

Microsimulation Models

Microsimulation (or microscopic) traffic simulation models use a detailed description of the movement of each individual vehicle in order to model traffic at a very detailed level. Microsimulation software is often used to evaluate traffic information, management, and control systems. Microsimulation models represent all related systems that affect traffic, such as traffic control and traffic guidance. Traffic control includes fixed and actuated traffic signals, ramp metering, and restricted access lanes and facilities.

In order to model the response of the drivers to information, microsimulation models provide facilities to represent information dissemination devices, such as variable message signs, and models to capture the response of the drivers to the presented information. As microsimulation models act as the test-beds for intelligent transportation systems and in-vehicle technologies prior to their deployment, microsimulation models sometimes also include facilities to model such systems as advanced driver assistance systems (ADAS), vehicle-to-vehicle (V2V) and vehicle-to-infrastructure (V2I) systems, and pricing strategies.

Different types of vehicles are also modeled, including passenger cars, commercial vehicles, powered-two-wheelers, public transport vehicles, and emergency vehicles, as well as different types of drivers. Modeling of pedestrians is a more difficult challenge, but most commercial microsimulation software has begun integrating detailed pedestrian simulation components. The ultimate goal is to

model interaction among all of the various modes, such as how buses and trams interact with passenger vehicles, or how all motorized vehicle modes interact with pedestrians and bicyclists.

Microsimulation models have been developed for more than 60 years, and a large number of mature microscopic models are widely used today, including commercial software such as AIMSUN, PARAMICS, TransModeler, and VISSIM; software supported by authorities, such as CORSIM, and academic- and research-oriented software, such as DRACULA, MITSIMLab, and sumo. One of the key prerequisites of microsimulation models is their detailed network representation. The information that is required when representing a traffic network for a microsimulation model is much more detailed than it would be for a less detailed model, such as a mesoscopic or macroscopic model. Typically, besides links, nodes and lanes, the information that is required includes lane connections, turning movements, and location and settings of traffic control devices.

Driving Behavior

Driving behavior in microscopic simulation models transcends three levels: (1) a strategic level in which the driver decides how to traverse the network to reach the destination, which is commonly modeled using route choice models; (2) a tactical level, in which the driver attempts to implement a strategic plan, such as determining the appropriate lane changes; and (3) an operational level, in which the driver performs the actual maneuvers, such as gap acceptance and acceleration, that will enable the necessary tactical decisions.

In terms of the strategic level, some of the initial models did not represent paths but used instead intersection turning proportions to determine vehicle movements across the network. Therefore, these models were not suitable to model route guidance applications.

However, modern traffic microsimulation systems have graduated to the loading of demand, using origin-destination tables, and the use of route choice models (usually logit-type, discrete choice models) to determine the paths that the vehicles follow as they traverse the network. If information is provided to the drivers, then these models also consider how the drivers respond to this information.

Acceleration

The acceleration of a driver depends on several parameters, including characteristics of the driver, the vehicle, and the road geometry, as well as surrounding traffic conditions. In general, acceleration models can be classified into (1) car-following models, which describe the behavior of drivers in response to the behavior of the preceding vehicles and (2) general acceleration models, which describe driving behavior even in non-car-following conditions.

Car-following models were developed in the early 1950s by Reuschel and Pipes, who developed simple linear models of car-following behavior. More elaborate models were developed in the late 1950s by the General Motors Group, based on comprehensive field experiments. This line of research led to the development of a family of car-following models that postulate that the behavior (response) of a driver is determined by the behavior (stimulus) of the leading vehicle.

These models at time “ t ” follow this general form: $\text{Response}(t+T) = \text{Sensitivity} \times \text{Stimulus}(t)$, where T is a time-lag corresponding to the following-driver delay; for example, the time to assess the stimulus from the preceding vehicle and respond to it. This general family includes several types of models based on a number of variations: (1) type of response, such as speed or acceleration; (2) type of stimulus, such as speed, distance, or acceleration; and (3) sensitivity of the following driver. Simple models of this family have been criticized because they may lead to unrealistic or inconsistent traffic conditions.

Depending on the formulation of each of these terms, models can overcome these limitations and result in conditions that are consistent with macroscopic traffic theory. Still, there are some limitations with this family of models, because they assume that drivers follow the preceding vehicle even when the spacing between them increases, and they also assume perfect perception of the stimuli and perfect reaction to them.

Several other families of models have also been proposed to address these limitations, including the psycho-physical models, which introduce a perceptual threshold that defines the minimum value of the stimulus following drivers can respond to. Although acceleration and car-following models represent a mature field, there are still new models being developed, such as rule-based models, the intelligent driver model (IDM), and mixed-flow models.

Lane Changing

Lane changing behavior is another important part of microsimulation that has received considerable interest, although less interest than that of acceleration behavior. A common distinction is to classify lane changes as mandatory and discretionary. Mandatory lane changes are performed when the driver must change lane in order to, for example, exit at an off-ramp, avoid entering a restricted-use lane, comply with lane-use signs, or avoid an incident.

Discretionary lane changes, in contrast, are the result of a decision by the driver who perceives the driving conditions at the target lane are preferable to staying at the current lane. An inertia term to changing lane can be considered when evaluating the perceived value of each lane.

K. I. Ahmed has developed a general lane-changing model framework that captures mandatory and discretionary lane-changing behavior. The lane-changing process is modeled in three levels: (1) decision to perform a lane change, (2) choice of the target lane, and (3) decision to accept a gap in the target lane. The model allows different gap acceptance parameters for discretionary and mandatory situations. Variants of these models also exist, such as forced merging models, which describe the behavior of drivers who need to make a lane change in heavily congested situations in which no acceptable gaps naturally exist.

Gap Acceptance

Besides lane changing situations, gap acceptance becomes relevant in various situations in microsimulation, such as unsignaled intersection behavior models. Gap acceptance models are typically formulated as binary choice problems, in which the driver either accepts or rejects a given gap. This decision is based on an unobserved critical gap, which, in general, would vary in the driver population. This process can be enhanced with an impatience function to mimic the fact that a driver who has already passed on a number of gaps might become more impatient and frustrated and accept a smaller gap than those already rejected. One practical way to model this is through a decaying critical gap function, in which critical gaps decay with waiting time or the number of rejected gaps. Ahmed specified and estimated models that jointly model lane changing and gap acceptance.

Integrated Models

Modeling lane changing, gap acceptance, and other decisions independently implies that drivers perform these tasks in isolation. In reality, however, drivers may adapt one aspect of their driving behavior to facilitate another task. For example, a driver might decelerate, not because of the behavior of the preceding vehicles but in order to perform a lane-changing maneuver.

Integrated models that unify the elemental microsimulation models have therefore been developed to address these limitations. For example, researcher T. Toledo presented a framework integrating short-goals, short-term plans, and tactical maneuvers. The process is as follows: the driver develops a short-term goal (for example, to change lane) and devises a short-term plan (for example, determine a target lane) to achieve that goal. The short-term plan is realized through a maneuver. A sequence of steps might be required to accomplish that goal; for example, the driver might need to first accelerate in order to reach an acceptable gap between two preceding vehicles before being able to perform the desired lane-changing maneuver. Depending on the model formulation, these decisions might be sequential, conditional, or nested.

Limitation and Challenges

Microsimulation models behave well in many situations and provide valuable tools in which new systems, such as intelligent transportation systems, can be evaluated and optimized prior to their application and deployment. However, there are situations that cannot be easily modeled by microsimulation models.

Road parameters that might affect traffic conditions are often not well modeled. One such example is road geometry, where the impact of the lane width and roadway gradient are usually not considered. Also, vehicles are assumed to move in a specific lane, and their lateral movement (which, in reality, does play a role) is usually ignored.

This may not be a big problem in situations where lane discipline is followed. However, when lane discipline is relaxed, which occurs in many developing countries, a specific link might, in effect, have a varying effective number of lanes (for example, four or five vehicles might squeeze side-by-side on a three-lane road). This flexibility, however, cannot be captured by conventional microsimulation models.

Further, modeling of pedestrian flow, as well as two-wheelers, is also further behind the modeling of cars. This might not represent a major concern in Europe or the United States, but in certain developing countries where a large fraction of traffic may be composed of two-wheelers and nonstandard-sized vehicles, the ability of standard microsimulation models to reflect reality could be compromised. Naturally, new flexible-lane microsimulation models are being developed in response to these needs.

Modeling road safety has become a very important research and policy topic, and microsimulation models are attractive tools for modeling road safety. However, there are some challenges that limit their widespread use. An important limitation is that most well established car-following models are inherently crash free; that is, the following vehicle would stop before crashing into the preceding vehicle. (Models that overcome these limitations are being developed.) Still, the evaluation of the safety conditions can be performed based on secondary proxy measures, such as the time-to-collision, the distributions of the acceleration or speed, and the extreme acceleration and speed values.

Calibration and validation of microsimulation models are more demanding than that of mesoscopic and macroscopic models, because they typically include a much larger number of parameters and require more data. The overall cost of developing a microsimulation model (including time, resources, and data) is typically much higher than it would be for developing a mesoscopic or macroscopic model. Therefore, the decision on which type of model will be used for a specific application should carefully weigh the benefits of the additional granularity and detail versus the higher costs.

Mixed-Mode Transit Systems

Mixed-mode transit systems, in which two or more modes of transportation are employed, seek to merge the benefits of various choices available to create a journey that is greater than the strength of its parts. Many mixed-mode transit systems seek to reduce reliance on the automobile and instead to encourage travelers to use a variety of other options, which may include walking, bicycling, rail, ferry, or other modes of transportation. The combination of two or more modes of travel also serves to offset the relative deficiencies of individual methods. As interest in sustainable practices continues to grow, mixed-mode transit systems will undoubtedly continue to play a role in transportation planning and policymaking decisions.

Background

Since the advent of automobile travel, many of the formerly popular travel modes have fallen into disfavor. While certain options used before the popularity of automobiles, such as the horse and carriage, have become marginalized, other modes of transportation—such as rail, bicycling, walking, and buses—are less environmentally harmful and still readily available. It becomes the mission of policymakers and planners to devise ways to encourage the public to

use modes of transportation that are more sustainable, even though they might not be as convenient as the door-to-door service offered by the automobile. To encourage commuters to leave their automobiles, alternative transportation options must be devised that are practical and cost-efficient.

Mixed-mode transit systems combine a variety of extant transportation options with one another to create a transportation option that is less damaging to the environment while also remaining convenient to the traveler. Existing travel modes, whether light rail, bus lines, roads or sidewalks, are used together to reduce the traveler's dependence on the automobile. Because many metropolitan areas are composed of multiple jurisdictions and decisions involve multiple agencies, mixed-mode transit systems require cooperation between different groups with authority to make decisions. In order to entice travelers to use the mixed-mode transit system, governments and agencies may offer such benefits as free parking, reduced fares, and other incentives to travelers using their systems.

Mixed-Mode Commuting

In many metropolitan areas, train or light-rail systems are the fastest and most efficient means to

move travelers. When mixed-mode transit systems are able to get travelers to eschew the single-passenger automobile and instead take all or part of their journey by train or light rail, the system reduces congestion, cuts down on pollution, and encourages environmentally sustainable behavior. Some mixed-mode transit systems seek to eliminate the automobile from most journeys, while others merely look to reduce its use. The goal set by a given transit system will depend upon commuter behaviors before the mixed-mode initiative is begun. Different scenarios play out better in different locations and with different groups, making planning essential.

Automobile travel is highly popular with commuters for a variety of reasons. Some of these reasons are unique to the individual, such as convenience and personal preference, but others have been greatly influenced by societal actions, such as the underpricing of the costs of automobile travel through federal and state tax subsidies to roads and freeways. As a result of these subsidies, the true costs are borne not by the user, but by society as a whole.

Proponents of mixed-mode transit systems use both incentives and deterrents to decrease commuters' reliance on the automobile. Incentives might include providing convenient parking for a

This glass bikestation outside the Union Station rail line in Washington, D.C., is a form of bike-and-ride system meant to encourage mixed-mode transit. The building provides safe storage for more than 150 bicycles at a time so that bicycle riders may make use of trains, the metro, and other transit nearby or visit surrounding areas on foot.

reduced price, giving transit users reduced fares, or making other changes that make mixed-mode transit more convenient and attractive. Deterrents could include reducing travel speed through speed bumps, reducing parking through various restrictions, prohibiting motor vehicles at certain times of the day, or enacting tolls for use of the roads leading into or through the central business district. The complexity of the incentives and deterrents will depend on how well the mixed-mode transit system is meeting its ridership goals.

Park-and-Ride/Kiss-and-Ride Systems

One of the most common ways planners and policymakers encourage mixed-mode transit is through implementation of a “park-and-ride” system. Park and ride is a way of encouraging commuters who would otherwise drive to their location to take a train, light rail system, or bus for part of their journey. Planners and policymakers provide car parking lots at train, light rail, or bus stations, permitting commuters to leave their cars for free or at a reduced charge. A slightly different method of encouraging the use of trains, light rail, or buses is termed *kiss and ride*. This is a designated area, close to where passengers board the transit mode, that allows the commuter to be dropped off or picked up by a personal vehicle; the driver usually must stay with the vehicle while waiting for the commuter. Both park-and-ride and kiss-and-ride systems are effective at encouraging commuters to take mass transit.

A system that is related to park-and-ride and kiss-and-ride programs is called “bike and ride.” Bike and ride is similar to the others in that it seeks to encourage mixed-mode travel. Bike-and-ride programs provide secure parking or storage for commuters’ bicycles. Because many bicycle riders are reluctant to leave their property unattended and risk vandalism or theft, bike-and-ride programs might provide some sort of monitoring or other security system that will protect the bicycles. Some bike-and-ride systems, especially, but not limited to, those run by bus lines, permit bicycles on the transit vehicle. On buses, the storage is sometimes provided on a rack on the front of the bus; on trains and light rail systems, storage space is usually provided near the doors. Again, bike-and-ride programs are successful when they attract commuters who would otherwise take an automobile and result in reduced congestion and pollution.

Other Mixed-Mode Transit

In large metropolitan areas, extensive railway and bus systems often exist separately. Those cities that seek to encourage mixed-mode transit systems link together their various systems. Doing so enables commuters to reach more destinations than they would by traveling exclusively on the train, light rail, or bus. A specific way of linking the two or more systems is to use feeder buses to direct commuters to train or light-rail systems. Feeder buses run through neighborhoods with a high density of residential units, and pick up commuters who might find it too far to walk to a train or light rail station. To encourage the use of feeder buses, they are scheduled so that they arrive at the train or light rail station shortly before departure times for outgoing trips and shortly after arrival for return trips. This reduces the time commuters must wait and increases their overall satisfaction with the dual-mode process.

To encourage car drivers to use more efficient and environmentally beneficial transit for long-distance journeys, some trains and ferries are constructed with the ability to carry automobiles as well as passengers. While planners and policymakers understand that vacationing families might prefer to have access to an automobile while on holiday, that vehicle does not need to be the only mode used for the journey. Passenger trains that have the capacity to carry automobiles are sometimes referred to as “motorail,” and they are especially attractive to people planning a stay of several months at their final destination. Ferries, which often can save travelers time when compared to driving the entire route, are another effective means to reduce congestion and gridlock while encouraging sustainable practices.

Transit Centers

Transit centers often play a key role in encouraging the use of mixed-mode transit systems. Transit centers assist in reducing congestion, pollution, and gridlock by allowing commuters easy access to two or more modes of transportation in one location. While location ultimately plays the largest role in an individual’s decision whether or not to use mixed-mode transportation, effective planning and policy decisions can assist in improving the attractiveness of the commuter’s ultimate choice. In order to entice users to transit centers, many such locations have found it effective to offer a variety of amenities to travelers utilizing the facility. These include

Jodhpur, India, has well established rail, road, and air networks connecting it to other major cities in the country; however, it is still common to travel by using a camel to pull a cart.

newsstands, coffee shops, bars, restaurants, dry cleaners, flower and gift shops, and other goods and services that are popular in the community being served.

Benefits and Problems

Mixed-mode transit systems combine the advantages of various modes of travel while reducing some of the disadvantages of each. An effective park-and-ride system, for example, permits commuters to travel from their homes to their final destination conveniently while also reducing crowding on the road by providing easy access to a train or light rail. Those who travel by mixed-mode transit systems often enjoy considerable savings by avoiding areas where automobile parking is prohibitively expensive. At the same time, people who must travel by automobile find that the streets are less congested than would otherwise be the case.

Because train, light rail, bus, and ferry systems incur certain fixed costs whether they are full or not—such as fuel, operators, depreciation of the equipment, and the like—mixed-mode transit systems that increase ridership on mass transit help cover more of those costs.

In some regions, however, mixed-mode transit systems prove ineffective. For example, any mixed-mode transit system that relies upon bicycles or walking will be at a disadvantage for large portions of the year in areas with frequent inclement weather.

Additionally, when one mode of a journey experiences failure, such as when a train is late, the other modes can be disrupted to the extent that a commuter is left stranded. Planners and policy makers are well served to work diligently to minimize such disruptions.

Mobile Emissions

Motorized transport creates emissions in the form of gasses, particles, and noise. While many of these arise directly from fuel combustion, emissions are also created through evaporation and abrasion from different vehicle parts. This entry pertains to airborne emissions generated by motorized surface transport modes, that is, roads, rails, and in shipping. It discusses the main emissions from mobile sources and the factors that influence types and levels of emissions. It also touches on the adverse effects of mobile emissions. The text focuses on emissions associated with vehicle operation. Emissions arising from other processes connected to motorized transport are not within the scope of this entry, although they also play an important role in social

and environmental contexts. Examples include gases, particles, and accidental spills connected with the extraction, refinement, and processing of fossil fuels, and particles and noise arising from the creation and maintenance of transport infrastructure.

Types of Vehicle Emissions

The main component of mobile emissions is carbon dioxide (CO_2), the transport sector's main contributor to climate change. Unlike all other mobile emission components, though, CO_2 is not directly toxic to humans or ecosystems. It is thus generally considered separately and is not covered by this article.

The major components of tailpipe emissions that are of local or regional concern are the following:

Carbon monoxide (CO). CO forms through incomplete combustion of carbon-containing fuels. Introduction and enhancement of vehicle emission standards, catalytic converters and better fuel quality have significantly lowered CO emissions in developed countries. CO can be used as a tracer gas for the dispersion of vehicle emissions because it is comparatively inert, that is, it does not chemically interact with other substances in the atmosphere.

Nitrous oxides (NO_x). NO_x consist of nitrogen dioxide (NO_2) and nitric oxide (NO), both by-products of combustion. Nitric oxide is generally quickly oxidized to form NO_2 after it is released into the atmosphere. NO_2 reacts with both oxygen and volatile organic compounds to form ozone.

Particulate matter (PM). PM does not consist of a single chemical substance but is a collection of both solid and liquid aerosols with different chemical and toxicological qualities. The primary components of PM in mobile emissions are a direct result of fuel combustion, including residues from the incomplete burning of carbon compounds. Secondary PM is formed through chemical reactions from engine emissions after their release from the combustion chamber, and contains nitrogen and sulfur compounds. PM is generally classified by particle size rather than composition. PM_{10} describes particles with a diameter of 10 μm and below (1 μm = 1 micrometer = 1 millionth of a meter). $\text{PM}_{2.5}$ denotes all particles equal to or below 2.5 μm in diameter. Thus $\text{PM}_{2.5}$ is a subclass of PM_{10} . The two size classes are often dealt with separately because PM's effect on

human health relates not only to its composition but also to the particles' size. The smaller they are, the farther the particles can penetrate into the human body, and the worse are the health effects associated with them. The combustion of diesel fuel is associated with greater PM emissions than gasoline.

Volatile organic compounds (VOCs). VOCs contribute to ambient air pollution as by-products of combustion. Vehicle fuels typically contain up to several hundred different VOCs, including, for example, benzene and polyaromatic hydrocarbons, many of which are known carcinogens.

Sulfur dioxide (SO_2). SO_2 is formed during combustion of sulfur-containing fuels and is a major contributor to the phenomenon of acid rain. In Europe and North America, fuels used in land-based transport are no longer permitted to contain large amounts of sulfur (current limit for liquid fuels for land transport in the European Union and proposed by the U.S. Environmental Protection Agency for 2017 is 10 parts per million or 0.001 percent), although heavy diesel used in shipping is subject to much less stringent limitations (limit of 3,500 parts per million or 3.5 percent permitted for international shipping by the International Maritime Organization). Most current global SO_2 emissions from transportation are thus attributable to the shipping sector.

Lead (Pb). In the past, lead was added to gasoline as an antiknocking agent to prevent engine damage from irregular combustion and to improve performance. It has been banned as an additive to fuels for road transport in North America and Europe, but can still be found in other fuel types, including fuel for railway locomotives, shipping, and mobile off-road equipment used in farming, construction, forestry, and other industries, as well as in aviation fuel.

Ozone (O_3). O_3 is not a component of primary mobile emissions, but transportation is the biggest emitter of NO_2 , which, together with ambient oxygen, is the main precursor of this secondary pollutant. Ozone is formed under solar radiation and is one component of so-called photochemical smog.

Smog. Smog is a phenomenon strongly associated with mobile emissions, but the term does not actually describe a particular type of primary or secondary

pollutant. The word is a combination of “smoke” and “fog,” and was in the past mostly associated with smoke from wood and coal burning. Now, photochemical smog associated with solar radiation and reduced convection in the lower atmosphere is more common, at least in Europe and North America.

Other sources. In addition to combustion, there are several other sources of emissions directly associated with the use of motorized vehicles:

- *Evaporative losses.* These are mainly composed of VOCs in gasoline fuel vapors emitted as a result of the following effects: diurnal losses due to temperature changes during the course of a day; running losses due to heat from the running engine; hot soak losses created by heat dissipating from a cooling engine; and cold soak losses from a resting vehicle, as a result of, for example, leaky fuel pipes.
- *Abrasion.* The wear of tires, brakes and clutches (in manual-transmission cars) creates PM that contains heavy metals, among other substances.

Tubes inserted into a catalytic converter allow researchers to sample emissions at the Oak Ridge National Laboratory. Engineers of the 2007 Dodge Ram heavy pickup truck used this test to help the truck meet 2010 emissions control standards three years early.

- *Resuspension.* Air turbulence caused by moving vehicles and the contact of tires with the road surface causes the resuspension of particles that have settled on or near the road. This PM generally contains both primary and secondary particles from mobile emissions, as well as other PM from the ambient air, for example, from stationary fuel combustion in power stations, domestic heating, or biological material such as pollen and fungal spores. The use of off-road mobile equipment in agriculture, forestry, and construction also creates PM from the vehicles, as well as dust from disturbed ground.

Factors Influencing Vehicle Emissions

The composition and amount of emissions generated per vehicle kilometer or mile depend on a number of different factors:

Size and type of vehicle. The vehicle weight and its load (passengers and/or freight), as well as its aerodynamic resistance (shape; loads on decks, trailers or roof racks, etc.), have a major influence on the amount of fuel used and on the emissions created per unit of distance.

Engine characteristics. An engine's technology, age, size, and state of repair influence fuel consumption and the efficiency of combustion. In many countries, legal emission standards for new vehicles have resulted in significantly improved tailpipe emissions over past decades.

In 1992, the European Union, for example, mandated EURO emission standards for new vehicles sold in EU member states. They regulate exhaust emissions of CO, NO_x, VOCs, and PM, and apply to passenger and light-duty vehicles, as well as heavy-duty vehicles and off-road mobile equipment, rail locomotives, and vessels used on inland waterways. The EURO 5 standard in 2013 limits tailpipe emissions of PM to 5mg/km for both diesel and gasoline engines. EURO 4 had no PM standard for gasoline; for diesel engines; the value represents an 80 percent reduction compared to EURO 4.

Electric vehicles create no tailpipe emissions or evaporative losses, but abrasion and re-suspension still occur. The emissions associated with their operation vary depending on the power source

used to generate the electricity they utilize, either directly (for example, electric locomotives and trams) or for charging their batteries (for example, electric cars and trucks).

Catalytic converters oxidize some of the CO and hydrocarbons emitted by gasoline engines to CO₂ and water, while diesel particulate filters remove some of the PM from diesel exhausts. Depending on the technology used, these filters can at the same time increase NO_x emissions, though.

Fuel type and quality. For the same amount of fuel burned, diesel engines create much more particulate matter than do gasoline engines, while the latter emit more VOCs. Fuel standards and quality also play a substantial role in influencing emissions created. One example is the different sulfur content of fuel for land transport versus sea shipping (see above).

Speed and driving conditions. Speed is a strong determinant of fuel use and thus emissions per distance unit. Emissions are normally highest at very low and very high speeds. A steady speed of 50 to 60 miles per hour (80 to 95 kilometers per hour) would theoretically minimize tailpipe emissions from a passenger car. In contrast, a vehicle that achieved a comparable average speed but which alternated between higher and lower speeds would create higher emissions. Similarly, driving styles and driving conditions characterized by alternating bursts of acceleration and deceleration (for example, stop-and-go traffic, abrupt stops and starts at intersections) result in considerably higher emissions. In international shipping, increasing fuel costs have given rise to a practice called slow steaming; ships travel at a lower speed than engine and conditions would allow, resulting in fuel savings and reduced emissions.

Effects of Vehicle Emissions

Local and regional air pollution resulting from mobile emissions can have severe impacts on the health of humans, as well as ecosystems. An association between chronic exposure to such emissions and increased morbidity has been found in both children and adults. Experts generally also agree that there are no levels at which such exposure can be considered safe and that mobile emissions are responsible for significant numbers of premature deaths, especially in urban areas. Primary and secondary mobile emissions, furthermore, contribute to disrupting the

nutrient balance in natural ecosystems and making plants more susceptible to diseases.

Mode Choice Models

Mode choice models estimate the share of travelers using each mode of transportation or, in freight transportation, the share by mass, volume, or other related measures. Mode choice models can be aggregate models estimating the percentages of trips used by each mode for a given set of trips or disaggregate models estimating the probabilities of each mode for a specific trip.

Mode choice is one of the most important travel choices an individual makes in terms of sustainable transportation development. If people change behavior to choose more environmentally friendly modes, including public transport, walking, and cycling, rather than private cars, the entire transportation system will become less congested and more sustainable.

Policymakers and transportation planners use mode choice models to a priori evaluate the effectiveness of new transportation infrastructure and services, as well as various transport policies, by estimating mode share shifts in response to new or improved services and policies. Estimating and analyzing such models can help policymakers identify the variables that will encourage shifts to more sustainable modes, including public transportation, cycling, and walking, thus enabling them to better prioritize investments in transportation.

Aggregate and Disaggregate Approaches

Aggregate model choice models take into account many variables about each possible mode of transport the traveler has available for the trip, such as travel time and cost, and estimate the proportion of travelers that would use each mode of transport (for example, 70 percent by car and 30 percent by public transport). This is usually estimated for each origin-destination pair, for a specific period of the day, and for a specific trip purpose.

To better understand travel behavior and the factors that will motivate individuals to shift to more environmentally friendly modes, most mode choice models are disaggregated discrete-choice models. These models have several important advantages over the aggregate approach because they explain why an individual makes a particular choice given her/his circumstances and are, therefore, better able to reflect changes in choice behavior because changes in individual characteristics and attributes of alternatives.

The aggregate approach, in contrast, rests primarily on statistical associations among relevant variables at a level other than that of the individual. The disaggregate approach is more suited for proactive policy analysis because it is causal, less tied to the estimation data, and more likely to include a range of relevant policy variables. Disaggregate discrete-choice models estimate the probabilities that a traveler making a specific trip from zone O to zone D in time period t for purpose p will choose a specific mode m of travel from a given set of available modes c .

In many practical applications, the model is estimated based on disaggregate data (for example, based on individual trips) and then applied in a semiaggregate approach. In this approach, given a trip table of a specific purpose and time of day for each origin–destination, the model will predict the

shares of each mode for each socioeconomic group. Advance travel–demand models move more and more toward agent-based approaches with a full disaggregate application.

In the traditional four-step travel demand modeling, mode choice modeling is the third step following trip generation (How many trips are generated?) and trip distribution (How they are distributed in space?), and preceding trip assignment (Which routes they are using?). When time-of-day modeling precedes mode choice modeling, the latter can account for the level of service for the actual time of day.

Other Model Systems

In more advanced travel-demand model systems, known as activity-based models, travel decisions become part of a broader activity scheduling process based on modeling the demand for activities rather than merely trips. These models estimate the travel choices of each trip segment within the context of all trips taken during a day, or at least within a tour, which is usually defined as a set of subsequent trips starting at home and ending at home. While this complicates the task of mode choice modeling, it also provides more realistic results, because the mode of each trip segment depends on the modes of the other segments of the tour and other attributes of the tour.

Most choice sets include, at a minimum, public transport and automobile. More advanced models include various submodes of public transport, including distinguishing between local bus, express bus, light rail, and heavy rail. Choice sets can also be defined by access and/or egress modes. These usually include park and ride, kiss and ride, bus, and walking. The analysis of transit auto access is very important in the context of analyzing modal shift to public transportation of people with auto availability.

With increasing interest in sustainable transportation, many models also include nonmotorized modes, mostly walking and cycling. The inclusion of all these modes means that the model can easily have a large number of alternatives. Identification of the relevant alternatives (the choice set) depends on the transport system under study, the policy at question and data availability. For example, intracity models will include modes that would not be included in intercity models, such as walk and cycling, while the latter will include modes such as high-speed rail.

In mode choice models, the choice set must be identified for each decision maker, because not

all modes are available for all trips. Modes can be unavailable because of an objective impossibility; for example, driving is not a possibility for a person without a driver's license. They can also be unavailable because they are not perceived as an alternative for a specific trip; for example, heavy rail will not be considered for a trip of a few blocks. When there are a large number of alternatives where some share common attributes, it is common to define nested model structures.

In an example of a nested model structure, at the highest level, the person may choose between private auto and public transportation. In the next level, he or she may choose between driving alone and carpooling if he or she chose private auto, or between bus and rail if he or she chose public transportation. In the last level, the person may choose between various access modes.

Types of Variables

Mode choice models have two main types of explanatory (independent) variables: (1) attributes of the individual and (2) attributes of the alternative travel modes, also considered as policy variables. These two types of variables can also appear in interaction; for example, it is common to include a variable of modal cost divided by income to represent the travel cost relative to one's income.

Attributes of the decision maker are mostly socioeconomic attributes, such as gender, age, income, car availability, and life cycle. Life-cycle variables represent the family stage in life, such as presence and age of children, and working status of the household members. It is common to segment the population to various markets and estimate a model for each market (market segmentation) to account for the different values different markets of the population give to different attributes. Common examples for market segmentation are by auto ownership and income. Another dimension of segmentation is by trip purpose, which represents the different behavior in mode choice decision making for different trip purposes, such as work-related, commuting, shopping, and leisure.

Most attributes of the alternative modes are level-of-service measures describing the level of service they provide to the traveler. These include travel time, travel cost, number of transfers, service reliability, and others. Travel time is usually decomposed into various components—such as

in-vehicle-time, wait time, transfer time, and walking time—because different persons may value each of these differently. Attributes that have negative coefficients usually represent disutility for the traveler. Level of service variables depend on the specific route the traveler will choose to take under each choice of mode. This is done by using the expected utility of the route choice, which, in logit or nested logit models, is the log-sum variable.

Another type of attribute is alternative-specific constants known as modal preferences variables. They account for qualitative characteristics of each mode or for perception differences among modes. For example, a metro may have a higher perceived nonmeasured quality, such as comfort, than a bus.

Value of time (VOT) is derived from mode choice models by calculating the ratio of the marginal utility of time:

$$\left(\frac{\partial U}{\partial t}\right) \text{ (the time coefficient in a linear utility)}$$

$$\text{and the marginal utility of cost } \left(\frac{\partial U}{\partial C}\right)$$

$$\text{(the cost coefficient in a linear utility)}$$

$$VOT = - \frac{\partial U / \partial t}{\partial U / \partial C}$$

This shows the marginal trade-off people are willing to pay in order to save time while keeping their utility at the same level. This value is important input for appraisal purposes to represent the monetary value that people put on their time. Ratios between other coefficients of level of service are also interesting, showing the relative importance of each attribute. For example, the coefficient of out-of-vehicle time is usually two to three times larger in absolute value than the coefficient of in-vehicle time, showing that people are willing to pay more to shorten their wait or walk time than their in-vehicle time. Finally, land-use and urban-form variables of the origin and destination of the trip can be proxies for both level-of-service variables, representing, for example, friendliness of walking, and for the individual, representing, for example, the type of neighborhood in which he or she is residing.

Process

The process of building a mode choice model involves several steps. The first step is model design, in which

the alternatives, model structures, independent variables, and the data to be used are defined. Mode choice models are usually based on the random utility theory. They assume that individuals make decisions that maximize their utility. The utility of an alternative mode is expressed as a function of the various explanatory variables. The most common models structured within this framework are the logit and the nested-logit models, but advances in computing have enabled more flexible model structures to be used, including probit and mixed logit.

The next step is model estimation, where the parameters of the model are determined to best fit the data. This is usually done using the maximum likelihood method. In this method, one tries to estimate the parameters of the model so that the predicted probabilities of the chosen alternative in the estimation data base will be maximized. The last step is model validation, where the model is validated against an independent data set and compared to available aggregate traffic data.

Mode choice models are best estimated using revealed-preference data, where the mode choices made by people are actually observed. These data are usually obtained by travel surveys, which are often conducted by local or national governments using different methodologies. Most common are travel-habit surveys, where respondents are asked to fill a travel diary in which they report on all trips they have taken during a period of time, usually at least 24 hours. For each trip they conducted, survey respondents are asked to report from where to where they traveled, at what time of day, and how long it took them, for what purpose, and by which mode.

However, many mode choice models are designed to evaluate new modes and policies that do not currently exist in a specific area. In such cases, it is common to use stated preference data, where people are faced with hypothetical alternatives and asked to state what would be their choice under various scenarios. These scenarios could include new modes or policies, as well as the level-of-service attributes of the various hypothetical alternatives presented to the respondent. To minimize potential bias with stated-preference data, it is recommended that a combination of revealed- and stated-preference data be used.

There are techniques to best utilize various sources of data and to benefit from the advantage of each type of data. Data on the modal level of service variables can be “skimmed” from the highway and public

transport networks for each origin–destination pair to form matrices. These are called skims because they are obtained from the paths by skimming along the paths accumulating the data. Networks can be skimmed for attributes including in-vehicle time, wait time, walk time, number of transfers, and fare.

Mode Share/Mode Choice

The term *mode* refers to the type of transportation used by an individual traveler or the type of transportation used to ship goods or other materials. For example, when individuals travel in an urban area, they might walk, bicycle, use public transit (for example, bus, light rail, commuter rail), use a personal motor vehicle (for example, car, truck, van, motorcycle), or use other modes. Similarly, freight may be shipped by truck, train, airplane, water vessel, or another mode.

Mode Share

Mode share is the portion of movement done by each mode. Mode share can be measured as the proportion of trips (that is, movements between an origin and a destination location), travel distance, travel time, or other measures of travel. Distance measurements tend to produce higher mode shares

for higher speed modes; trip-based measures tend to produce higher mode shares for lower speed modes. Some personal trips and freight shipments are multimodal, or use more than one mode between their origin and destination, for example, walk from origin to a bus stop, ride the bus, walk from a second bus stop to destination. Or a postal worker carries a package from origin to a shipping facility, package is shipped by truck to second shipping facility, postal worker carries package from shipping facility to destination.

It is common for analysts to consider the mode used for the longest distance between activities to be the primary trip mode. Mode shares can be derived for particular travel purposes (for example, mode share for travel to work or mode share for international exports) or particular travel groups (for example, mode share for low-income households or mode share for coal shipments). Mode shift refers to a change in the proportion of movement done by each mode over time.

According to the U.S. National Household Travel Survey, a private automobile was the primary mode used by individuals for approximately 84 percent of trips between activities in 2008. Other trip mode shares in 2008 included pedestrian (10 percent), public transportation (4 percent), and bicycle (1 percent). The U.S. Freight Analysis Framework, reports trucks were used to ship approximately 68 percent of all freight tonnage in 2011. Other freight shipment mode shares included rail (10 percent), pipeline (8 percent), multiple modes and mail (8 percent), and water (5 percent).

Mode shares vary by geography and time. The Chicago Metropolitan Agency for Planning 2008 Travel Tracker Survey shows that the personal trip mode share across the eight-county region was 80 percent automobile, 10 percent pedestrian, 9 percent public transportation, and 1 percent bicycle. However, the central Chicago trip mode share was 53 percent automobile, 26 percent pedestrian, 17 percent public transportation, and 2 percent bicycle. Considering time of day, the share of public transportation trips is highest during the morning and afternoon; nearly all late-evening trips in the Chicago region are made by automobile.

Mode Choice

Mode choice refers to the selection of a type of transportation to use for a particular purpose.

Cars on the Dan Ryan Expressway heading into Chicago in 2010. Outside of the city's center, personal trip mode share has been estimated at 80 percent automobile, 10 percent pedestrian, 9 percent public transportation, and 1 percent bicycle.

Traditionally, the travel time and cost of using a particular mode have been viewed as the primary drivers of personal and freight transportation mode choice. In recent years, travel behavior researchers have identified other factors that are associated with personal mode choices, including socio-economics (for example, automobile ownership, income, age, gender, and student status), built environment (for example, population and employment density, land-use diversity, roadway characteristics, and neighborhood design), natural environment (for example, weather, topography), attitudes (for example, personal enjoyment of particular modes, cultural influence/social pressure), and perceptions (for example, traffic safety, personal security).

Mode choices are typically analyzed using utility theory. Utility theory is the basis for discrete-choice analysis, which assumes that individuals or firms will choose the mode that is the most attractive among all available alternatives, based on relevant variables (for example, time, cost, comfort) and subject to random error that is not expressed by the variables considered. The family of discrete-choice models includes binary logit, multinomial logit, nested logit, and others. These models can be used to identify variables that are associated with individuals and firms choosing particular modes. They can also be used for forecasting future mode shares in order to predict the impact of transportation investments or other policy changes in a community.

Mode-choice analysis is often simplified to consider only those travel options that are currently available to individuals and firms. However, medium- and long-term decisions also influence mode choices. Individuals purchase or give up vehicles, change jobs, change family structure, and change home locations. Similarly, firms select locations, choose clients and markets, and purchase vehicle fleets, all of which change the relative attractiveness of different transportation options. To varying degrees, people and businesses make these longer-term decisions with future mode choices in mind.

Given the complexity of mode choices, transportation researchers and psychologists have also proposed frameworks to describe mode choice as a decision process. These frameworks include the theory of planned behavior, theory of interpersonal behavior, transtheoretical model, model of normative decision making, and comprehensive action determination model. Rather than treat the selection of a mode as a discrete choice, these theories suggest that mode choices may be subject to social norms, individual preferences, and the development of habits over time.

The operational theory of routine mode choice decisions integrates components of many of these frameworks. This theory describes how people choose transportation modes for routine travel purposes, such as local shopping or other errands. It suggests five steps in the choice process: First, “awareness and availability” determines which modes are viewed as possible choices for routine travel. The next three steps are “basic safety and

security,” “convenience and cost,” and “enjoyment.” These steps assess situational tradeoffs between modes in the choice set, and might be considered simultaneously or in sequence. The final step, “habit,” reinforces previous choices. Socioeconomic characteristics explain differences in how individuals view each step in the process.

Monorails

Monorails have proven efficiency and safety records, but they still face public perception or image problems. Some people think that monorails haven't proven their efficiency as a mass transit method because they are concerned about the practicality and safety of evacuating stranded passengers from overhead trains, and they believe that elevated monorails spoil urban landscapes. The Monorail Society and other monorail proponents counter that monorails are efficient, safe, cost effective, and environmentally friendly. The future expansion of monorail systems depends on overcoming public and taxpayer misconceptions about their cost and effectiveness as a mass transit system.

The Singular Monorail

A railroad transportation system based on a single rail acting as its sole support and guide way, a monorail system is often but not exclusively elevated and can be both manned and unmanned. Several designs of monorails are divided into straddle beam and suspended monorails. The straddle beam monorail, which has a train straddling a steel or reinforced concrete beam within the range of 2 to 3 feet wide, is the most common type of monorail. A carriage with rubber tires connects the beam on the top and both sides for traction and stability. The German company ALWEG popularized the straddle beam. A suspended monorail features a train with cars suspended beneath the wheel carriage with the carriage wheels riding inside the single beam. The French company SAFEGE offers a suspended monorail system. In the 1880s, German inventors Nicolaus Otto and Eugen Langen developed the suspended monorail which opened in the twin cities of Barmen and Elberfeld in the Wupper Valley in 1901, and it is still operating.

Monorail cars can come in a singular rigid format, articulated single units, or as multiple units linked into trains with cars that are wider than the guiderails that support them. Monorails are powered by linear induction motors and their cars are connected to the beam by bogies, which are wheeled wagon or trolley systems that allow the cars to safely negotiate curves. In contrast to some tram and light rail systems, modern monorails are separate from other traffic and pedestrians and, unlike other guided railroad systems, they are

guided and supported with the same single beam. They also do not use a pantograph, a single overhead wire on the roof with return current running through the track.

Monorail Systems

Metropolitan monorail systems are in operation in 178 cities around the world, with 20 in Asia. Ten monorail systems are located in Japan with the longest operational monorail line in the world, a 15-mile corridor in Osaka. The Chinese government is constructing a crisscrossing network of monorail corridors to expand the 28-mile Chennai, China monorail system that it estimates will be 186 miles long if it is completed according to plan.

Monorail systems have been operating since the 19th century, but in their pioneering years they were primarily short line systems that moved small amounts of freight and passengers. On June 25, 1825, the Cheshunt Railway in Cheshunt, England celebrated its grand opening, earning its place in history as the first passenger-carrying monorail. In 1876, the Sonoma Prismoidal, a 7-mile wooden monorail, was planned to be the first rail line built to connect Sonoma in northern California with a steam ship landing at the San Pablo Bay. Only 3.5 miles of the line with a 15-inch-high track were built between Norfolk and Sonoma, at a cost of \$4,500 per mile, half of the cost of contemporary narrow gauge railroads. Although the railroad operated from November 23, 1876, to May 5, 1877, promoter Joseph S. Kohn never realized his plans to extend the monorail to Sonoma Landing on the Petaluma River or build an elevated prismoidal rail along Market Street in San Francisco.

The oil boom of the 1870s in Pennsylvania produced a modified version of the monorail line running between Bradford and Gilmore. In 1878, oil company backers built the monorail to transport oil drilling equipment and people to Derrick City, with wayside stations added at Tarpot, Babcock's Mill and Harrisburg Run. Since the rotary engines lacked power, the builders decided to use a larger locomotive driven by local pistons. On January 27, 1879, as the train ran at high speed to demonstrate its effectiveness to company officials and onlookers, the boiler exploded and it crashed into a creek, killing the driver, fireman, and three passengers and severely injuring several others. The oil company abandoned the line shortly after the accident.
